NATURE

A WEEKLY

ILLUSTRATED JOURNAL OF SCIENCE

VOLUME XV.

NOVEMBER 1876 to APRIL 1877

"*To the solid ground*
Of Nature trusts the mind which builds for aye."—WORDSWORTH

London and New York:
MACMILLAN AND CO.
1877

LONDON
R. CLAY, SONS, AND TAYLOR, PRINTERS,
BREAD STREET HILL, QUEEN VICTORIA STREET

INDEX

BBAY (Rev. R.), Patenas or Grass Lands of the Mountainous Region of Ceylon, 398; Lowest Temperature, 471
bbott (Dr. Chas. C.), Pre-Glacial Man in America,, 274
bel (Prof. F.R.S.), Chemistry and Telegraphy, 321
bercromby (Ralph), Is Meteorology a Science? 510
bney (Capt. F.R.S.) "Instruction in Photography," 253; On the Photographic Image, 543
braham (Phin. S.), "Stone Rivers," 431
bsorption Bands, M. Lippich on, 209
bsorption of Light in the Blood, 362
Absorption of Organic Matter by Plants, 108
Accipitres of Canada," Vennor's, 546
Acoustics, Light, and Heat," by William Lees, Dr. W. H. Stone, 352
Actinophrys, 108
Adams (Prof. A. Leith), Sense of Hearing in Birds, 334; Gigantic Land Tortoises, 347
Aeronauts, French Schools of, 383
Africa: Piaggia's Exploration of, 89; Exploration of Central, 188; Antinori's Exploration of, 188; Portuguese Exploration of, 208; Cameron's "Across Africa," 277; The Berlin African Society, 283; Stanley's Exploration of, 480; Hydrography of W. Central Africa, 517, v. Bary's Expedition, 540
Agassiz (Prof.), the *Challenger* Collections, 256
Agriculture, French National School of, 128
Agriculture in the United States, 525
Air, Heated, 283
Airy (Sir G. B., F.R.S.), Ancient Solar Eclipses, 115; Solar Physics at the Present Time, 196
Aldis (W. Steadman), Owens College, Manchester, 509
Algæ: a New Parasitic Green, 416; of the Gulf of Finland, 459; of the Kara Sea, 461
Algeria, Sirocco in, 89
Algoid Swarm Spores, 15, 178
Alpenverein, German and Austrian, 68
Alpine Club, the Swiss, 383
Alpine Flowers, Collections of, 150
America, Traces of Pre-Glacial Man in, 274, 295
American Geographical Society, 345
American Journal of Science and Arts, 267, 286, 385, 541
Americanists, Congress of, at Luxemburg, 208
Ampère, Bust of, 69
Amphibia, Carboniferous, in Nova Scotia, 264
Amyl, Nitrite of, Dr. B. W. Richardson, F.R.S., 24
Anæsthetics, New Alcoholic, 209
"Andes and the Amazon," James Orton, 154
Aneroid Barometer, Improvement in, 460
Aniline in Photographs, 207
Animals, Colours of, 16
Antarctic, The Conditions of the, Sir Wyville Thomson, F.R.S., 104, 120
Antedated and Undated Books, 17
Antedon Rosaceus (*Comatula rosacea*), 7, 58, 158, 159, 197, 366
Antimony Pentachloride, action of, on certain Organic Substances, 282
"Anthracen," Auerbach's, 507
Anthropological Society at St. Petersburg, 363
Anthropology: Beitrage zur Anthropologie und Urgeschichte Bayerns, 89; Society at Munich, 89; Prof. Virchow on the present position of, 149; Paris School of, 149; Anthropological Institute, 131, 151, 171, 268, 307, 327, 387, 421, 483, 523, 543
Ants, Sir John Lubbock on, 386; Mr McCook on, 439
Apatite and Nephelin, 384
Aquarium, proposed, at Birmingham, 170
"Archæological Frauds," 150
Archer (S.), Mimetic Habits of Bats, 313
Archiv fur Anthropologie, 110
Archiv fur mikroskopische Anatomie, 111
Archives des Sciences Physiques et Naturelles, 542
Arctic Expedition, English: 1, 11, 68; Capt. Nares' Report, 24, Prof. Osborne Reynolds on, 87; Medals commemorative of, 89; Dr. Petermann's Map of the, 109; Wordsworth Donnisthorpe, 116, Dr. Petermann on the, 148; Natural History and Geological Results of the, 432; Sir George Nares on the, 480; the Blue-Book on, 505
Arctic Expedition, Payer's Narrative of the Austrian, 62, 81
Arctic Expedition, the German, 148
Arctic Exploration, 51; German Society for, 17; by Balloons, 148, Capt. Howgate's Method of attaining the North Pole, 284, 365
Arctic Seas, Tides of the, 562
"Are We Drying Up?" 6, 217
Argyll (Duke of, F.R.S.), Holly-Berries and Rare Birds, 273; Hibernation of Birds, 527
Asphronemus olfax, 265
Astronomical Bibliographies, 455
Astronomical Clock, a New, Sir William Thomson, F.R.S., 227
Astronomical Column, 14, 48, 65, 86, 107, 125, 146, 166, 186, 206, 243, 262, 281, 303, 323, 342, 361, 381, 414, 437, 457, 478, 500, 519, 531, 549
"Astronomical Myths," John F. Blake, 351
Astronomical Society. *See* Royal
Astronomy, Sidereal, Knobel's Catalogue of the Literature of, 48
Atkins (Edward), "Elements of Algebra," 115
Atlantic: Meteorology of the, 49; Temperature of the Northern part of the, 107; Physics of the, 263; Atlantic Ridge and the Distribution of Fossil Plants, 158; Atlantic Soundings, J. J. Wild, 377
Atmosphere of the Rocky Mountains, Dr. Henry Draper, 354
Atmospheric Currents, 294, 374, 450, 510
Atmospheric and Ocean Currents, 333
Atmospheric Pressure in Russia, 457
Auerbach (G.), "Anthracen," 507
Auroric Lights, G. H. Kinahan, 334
Australia, Drought in, 523
Austrian Arctic Expedition, Payer's Narrative of, 62, 81
Austrian *Novara* Expedition, Report on the, 261

Backhouse (T. W.), Spectrum of the New Star in Cygnus, 295
Baer (Karl Ernst von), Obituary Notice of, 138
Baer Medal, Award for 1877, 363
Bain (Alexander), Obituary Notice of, 218
Bakarganj, Beveridge's District of, 135
Ball Lightning, 539
Balloons: Large, at the Paris Exhibition, 501; Apparatus for Steering, 110; Sale of French, 266; for Meteorological Purposes, 458
Ballot (Dr. Buys), on a Mode of Investigating Storms and Cyclones, 216, the Physics of the Atlantic Ocean, 263
Baltic Provinces, Geological Map of, 70
Barkley (H. C.), "Between the Danube and the Black Sea," 134
Barometer, South Polar Depression of the, 157, 198, 253
Barometers: of Southern Russia, 49; Variations of, J. Allan Broun, F.R.S., 151; Distribution of, in France, 538
Barometric Range at High and Low Levels, 187, 275
Barometric Pressure, Experiments on, 502
Barth (Baron), Death of, 325, 344
Bashkirs, Anthropological Sketch of the, 382

Basking Shark, Prof. Henry J. Giglioli, 273 ; Prof. E. Percival Wright, 292
Basques, the, Rev. A. H. Sayce, 394
Batrachians, the Development of, without Metamorphosis, 491 ; Non-Amphibious, Rev. George Henslow, 548
Bats, Mimetic Habits of, S. Archer, 313 ; Protective Mimicry among, G. E. Dobson, 354
Bauer's "Philological Introduction to Greek and Latin," 74
Baxendell (Mr.), the Protection of Buildings from Lightning, 88
Bayeux Tapestry, the Comet of the, 126
Bears, Polar, Fight between two, 70
Beaver in Siberia, 265
Beckesheim (M.), Experiments with Nitro-Glycerine, 71
Beer : Pasteur's Études sur la Bière, 213, 249
Bees : Toads eating, 502 ; Origin of the Flying Powers of, 559
Beetles, Blistering, as a Cure for Hydrophobia, 264
Belcher (Admiral Sir Edward), death of, 461
Belfast, Working Men's Institute, 128
Belgium : Geographical Society, 128 ; Geological Maps of, 304; Geological Society, 304 ; Education in, 326 ; Hurricane in, 253
Bellynck (Prof.), Death of, 304
Belt (Thomas), Pre-Glacial Man in America, 295
Bengal, Cyclone Wave in, 261
Beni, Prof. James Orton's Exploration of the River, 17
Bennett (A. W.), European Polygalas, 5
Berkeley (Rev. M. J.), the Fungus Disease of India, 21
Berlin : Gorilla in, 51, 208 ; Additions to the Ethnological Museum, 89, 304 ; Anthropological Society, 169, 304, 364 ; Ethnological Objects at the Royal Museum, 208 ; Geographical Society, 345 ; Chemical Society, 211, 327, 367, 422
Berliner Astronomisches Jahrbuch, 362
Bernardin (Prof.), Classification of Fécules, 209
Bernese Alps, Orography of, 188
Bessel's Treatises, 414
Bethnal Green Museum, 18
Bettany (G. T.), on the Primary Elements of the Skull, 127
Beveridge (H.), the District of Bákarganj, 135
Bianconi (Prof.), Experiments on Ice, 69
"Bibliographia Caucasica et Transcaucasica," 71
Biela's Comet in 1805, 479
Binary Stars, 186, 414, 500 ; γ Centauri, 303 ; α Centauri, 510
Biological Notes, 15, 65, 108, 127, 167, 263, 324, 414, 438, 458, 558
Biology, Prof. Huxley's Lecture on the Study of, 219
Birds : Palmén on the Migration of, 465 ; Sense of Hearing in, Prof. A. Leith Adams, 334 ; can they Count? 345 ; Hibernation of, 465, 527 ; of Celebes, 559 ; Bird's Eggs, 502 ; Birds and Insects, Sense of Hearing in, 254, 292, 354
Birmingham (J.), the Suspected Intra-Mercurial Planet, 509 ; Occultation of Kappa Geminorum, 509
Bischofsheim Transit Instrument, 16
Bisons, the American, 167
Black Burgh Tumulus, Brighton, 131
"Black Drop," M. Ch. Andre on the, 285
Blake (John F.), "Astronomical Myths," 351
Blake and Tate's "Yorkshire Lias," 113
Blood, Absorption of Light in the, 362
Body-change, Relation of, to Temperature, 324
Bolide at Clerey, 69
Boltzmann (M.), on Gas Molecules, 306
Bombay, Meteorology of, 482
Bonney (Rev. T. G.), the Age of the Rocks of Charnwood Forest, 97, 137
Boomerang, the, 312, 510
Borelly's Comet, 431, 549
Boring, Deep, at Rheinfelden, 128
Boron and its Specific Heat, 283
Bosanquet (R. H. M.), the Hindoo Division of the Octave, 420
Boston (U.S.), Natural History Society, 192, 388
Botanic Gardens : Calcutta, 71 ; Brisbane, 190
Botanical Geography of Russia, 459
Bottomley (J. T., M.A.), "Dynamics," 467
Bowerbank (Dr. John Scott, F.R.S.), Death of, 481
Boxwood, the Supply of Russian, 345
Bradford Scientific Association, 560
Brahé (Tycho), Notice of, 405 ; his Portrait, 530
Brain, the Functions of the, Dr. David Ferrier, F.R.S., 73, 93 ; Action of the, 264
Braun (Alexander), Obituary Notice of, 490
Brazil, Geology in, 149
Bremen geographische Gesellschaft, 246
Bressa (Dr. C. A.), Prize instituted by, 207
Brighton Aquarium, 365
Brighton, Black Burgh Tumulus, 131
Brisbane Botanic Gardens, 190
Bristol, University College, 459
British Guiana, C. Barrington Brown's Camp Life in, 311
"British Manufacturing Industries," 54, 96, 445
British Museum : Semitic Remains in the, 247 ; the Estimate on the, 382
Broca's Stereograph, 558
Bronze, Steel, 522
Broun (J. Allan, F.R.S.), Variations of the Barometer, 151
Browallia elata, Supposed Self-Fertilisation of, 24
Brown (Rev. G.), Exploration of Polynesia, 246
Brown (C. Barrington), Canoe and Camp Life in Britisl Guiana, 311
Brussels Observatory, New Instruments for, 304
Buchan (Alexander), Greenwich as a Meteorological Observatory, 450, 528
Buckland (Frank) on the Breeding of the Salmon, 375
Bulletin de l'Academie Impériale des Sciences de St. Pétersbourg, 20
Bulletin des Sciences Mathématiques et Astronomiques, 332
Burial-Ground near Rauschenburg, Discovery of, 51
Burrows and Colton, "Concise Instructions in the Art of Retouching," 156
Butterflies of America, Edward's Work on the, 70

Cæsium and Rubidium, Atomic Weights of, 282
Calabria, Natural History of, 541
Calcutta, Report of the Royal Botanic Gardens, 71
California, Glacial Drift in, A. R. Wallace, 274
Cambridge, Natural Science Club, 70 ; Philosophical Society, 87, 132, 151, 444, 573 ; Natural Science Scholarships and Exhibitions, 70, 89, 322, 325 ; Lectures in Science at, 325, 540
Cambridge, Mass., U.S. : Science at, 432 ; Observatory, 201
Camelidæ, the evolution of the, 168
Cameron (Commander V. L.), "Across Africa," 277 ; Lecture at the Sorbonne, 305
Campbell (Lord George), "Log Letters from the *Challenger*," 290
Canada : the Emigrant and Sportsman in, John J. Rowan, 216 ; Catalogue of the Minerals of, 272
Caucasica and Transcaucasica, Bibliography of, 71
"Canoe and Camp Life in Brit. Guiana," Barrington Brown, 311
Cape Astronomical Results, 1871–1873, 478
Capercailzie in Northumberland, W. Topley, 7
Carbon Dioxide in Minerals, Variations of, 167
Carboniferous System of Northumberland, 189
Carboniferous Amphibia, in Nova Scotia, 264
Carnivorous Water-Beetles, Respiratory Functions of, 91
Carob, the, in Madras, 419
Carrick (Alick), "The Secret of the Circle," 155
Carruthers (Mr.) on Evolution and the Vegetable Kingdom, 467
Cast-Iron, 529
Caterpillar : J. A. Osborne, 7 ; Commensalism among, 264
Cayley's Elliptic Functions, C. W. Merrifield, F.R.S., 252
Celebes, Birds of, 559
Celts, Discovery of, in Gurnet Bay, 128
Cerebellum, the Functions of the, 438
Cetus, Red Star in, 281
Ceylon, Patenas of, 398, 548
Chad Basin, Races and Tribes of the, 550
Challenger Collections : Sir C. Wyville Thomson, F.R.S., 254 ; Prof. Agassiz on the, 256 ; Henry H. Higgins, 274
Challenger Expedition : Lord George Campbell's "Log Letters;" Spry's "Cruise of the *Challenger*," 290
Challenger Soundings and the "Lost Atlantis," 553
Chappell (Wm., F.S.A.), Just Intonation, 196, 430
Charnwood Forest, Rocks of, 78, 97, 116, 137, 470, 548
Chekanoffsky (M.), Death of, 50
Chemical Notes, 167, 282, 362, 520
Chemical Society : 72, 91, 210, 286, 327, 367, 420, 463, 523, 563 ; Goldsmith's Company's Grant to, 16 ; Research Fund, 88 ; Dinner, 459
Chemistry : Hofmann's Lecture on Liebig, 193 ; Eltoft's Combined Note-book and Lecture Notes, 195 ; the Article in th Encyclopædia Britannica, 269 ; Vacher's Primer of, 527
Chemistry and Telegraphy, Prof. Abel, F.R.S., 321
Chester Society of Natural History, 461
Chevreul (M.), Dinner to, 87
Chlorine, Action of, on Peroxydes, 283

istie (W. H. M.), Centralisation of Spectroscopy, 489
onometers, Ships', Parkinson and Frodsham, 470
tridium with True Reproduction, 458
chona Cultivation in India, George King, 446
cle, Books on Squaring the, 155
lang," the Vowel, 441
rke (Col. A. R.), Just Intonation, 253, 353
valina Szaboi, Dr. von Hantken's *Foraminifera* of, 115
nate, the Cause of Changes of, 17
nates: Former, D. Pidgeon, 275; Investigation of, T. Ste-
enson, 556
mbing Plants, Tendrils of, 558
ck: Public, in Paris, 169; a New Astronomical, Sir Wm.
homson, F.R.S., 227
cks, Pneumatic Tube applied to Regulating, 418
uds, Measurement of the Height of, 313, 431
de, the River, 99
l-fields of Nova Scotia, 462, 488
fee Cultivation in Coorg, 418
fee-leaves as a Substitute for Tea, 540
cenis Julia in Texas, Dr. L. Heiligbrodt, 339
orado, the Upper, Prof. A. Geikie, F.R.S., 337
our-blindness, 110, 346
ours of Animals, 16
ours, Accidental or Subjective, 384
ton and Burrows, "Concise Instructions in the Art of Re-
uching," 156
nber (Thomas), Evolution and the Vegetable Kingdom, 467;
orphology of *Selaginella*, 548
nbustion, Influence of Pressure on, 167
nets: The Fourth of 1857, 15; the Comet of the Bayeux
apestry, 126; Periodical Comets in 1877, 186, *206*; *De*
ico's, of Short Period, 206; of 1812, 323; the New Comet,
42, 361, 381; Borelly's, 431; D'Arrest's, 457; Biela's
omet in 1805, 479; of 1873 (Tempel), 520; Winnecke's,
20, 531, 549
nmensalism among Caterpillars, 264
npass-Plant, 298
npasses at the Tiflis Observatory, 109
nte (Prof. Joseph Le), Hog-Wallows, or Prairie Mounds, 530
rg, Coffee Cultivation in, 418
peland (Ralph), the New Star in Cygnus, 315, 361
al, Pink, Discovery of a Bed of, 128
al: Growth of, 418; Coralean Rocks of England, 347
doba, Observations at the Observatory, 531
nu (Prof. A.), the Spectrum of the New Star, 158
mos, 127
niology, Prof. Virchow on Bulgarian, 364
tinism in Austria, 384
cuses, Yellow, A. G. Renshaw, 530
okes' (Wm., F.R.S.), Experiments with the Radiometer, 224,
99; "Translation of Auerbach's Anthracen," 507
staceans, Eyeless, 559
ptogamic Flora of Russia, 459
stals, Prof. Maskelyne, F.R.S., on, 523
stallised Nitro-glycerine, Experiments with, 71
rystallography," Groth's, 372
koo and Swallows at Menton, Douglas A. Spalding, 528
nberland Scientific and Literary Societies, 129
nming's (Linnæus) "Theory of Electricity," 526, 549
nningham (R. O.), Hearing in Insects and Birds, 293
lones: of October 31, 1876, 89, 126; at Backergunge, 68;
t Chittagong, 69; Storm Waves of, 261, 311; Polar, 312
lones and Storms, on a Mode of investigating, Dr. Buys
allot, 216
gnus, a new Star in, 146, 166, 186, 206, 295, 303, 315, 361
hovicz (Prof.), Influence of Electricity on Certain Spectra, 70
rny (Dr. Francis), the Action of the Winds in determining
he Form of the Earth, 239

Albertis's Expedition to New Guinea, 165, 452
le (T. Nelson), the Rhætic Strata in the Southern Tyrol, 4
morseau's Tables of Jupiter's Satellites, 414
Danube and the Black Sea," Barkley's, 134
Arrest's Comet, 457
rwin (Charles, F.R.S.), Sexual Selection in Relation to
Monkeys, 18; "Geological Observations," 289; "The
Effects of Cross- and Self-Fertilisation in the Vegetable
Kingdom," Prof. Dyer, 329; Testimonial to, 356, 410
rwin (Francis), Hygroscopic Seeds, 374

Darwin (G. H.), Influence of Geological Changes on the Earth's Axis of Rotation, 360
Darwin'sche Theorien und ihre Stellung zur Philosophie, Religion und Moral, 176
Davenport Academy of Natural Sciences, 247
Davis (Capt. J. E.), Death of, 325
Dawkins (Prof. Boyd, F.R.S.) on Museums, 129
De Notaris (Guiseppe), Notice of, 561
Deas (James), the River Clyde, 99
Deep-Sea Manganiferous Muds, E. T. Hardman, 57
Deep-Sea Muds, John Murray, 319, 340
Deer, Persian, 66
Definiteness and Accuracy, Prof. P. G. Tait, 77
De Mosenthal and Harting, "Ostriches and Ostrich Farming," 176
Denmark, Geographical Society, 128, 188
Denning (Wm. F.), Radiant Points of Shooting Stars, 158, 217; Meteor of January 7, 1877, 335
Dental Anatomy, Tomes's Manual of, 161
Descent Theory, Weismann's Researches on the, 451
Deutsche geologische Gesellschaft, 208
De Vico's Comet of Short Period, 206
Dewar (Prof. James), Physiological Action of Light, 433, 453
Dionæa muscipula, Contractions of the Leaf of, 379
Diseases Germinated in Hospitals, 15
Disinfectants, Report of Russian Committee on, 16
Diurnal Barometric Range at High and Low Levels, 187
Dobson (G. E.), Protective Mimicry among Bats, 354
Dodge (Col.), "The Hunting Grounds of the Great West," 194
Dobson (Dr. Anton), Proposed Zoological Stations in Heligoland and Kiel, 57
Donnelly (Major), the London Industrial University, 519
Donnisthorpe (Wordsworth), the Arctic Expedition, 116
Double Stars: 14, 470; Variable Components of, 303; Lord Lindsay's List of, 381
Douse (T. Le M.), "Grimm's Law," Rev. A. H. Sayce, 309
Draper (Prof. H.), Photographs of the Spectra of Venus and α Lyræ, 218; Atmosphere of the Rocky Mountains, 354
Drew's "Northern Barrier of India," 396
Drosera rotundifolia, Abnormal Growth of, 18
Drummond (James), Death of, 208
Dreyer (J. L. E.), Tycho Brahe's Portrait, 530
Dumont (Andre), Geological Maps of Belgium, 304
Duncan (Wm. S.), Mind and Matter, 78, 295
Dun Echt Observatory Publications, 381
Duplex Telegraphy, an Account of, 180
Dupre (Dr. A.), Estimation of Urea of *Means of Hypobromite*, 399
Dutch *Society of Sciences, Gold Medal of, 207*
Dutch Guiana, *W. G. Palgrave, 311*
Dyer (Prof. Thiselton), Darwin on Fertilisation, 329; Morphology of "Selaginella," 489
"Dynamics," Bottomley's, 467
Dynamo-Magnetic Phenomena, 72

Earth: the Solidity of the, W. M. Williams, 5; Internal Fluidity of the, Prof. H. Hennessey, 78; Population of, 127; Action of the Winds in Determining the Form of, 239
Earth's Axis of Rotation: Influence of Geological Change on the, G. H. Darwin, 360; Possible Displacements of, 443
Earthquakes: at Irkutsk, 18; in Germany, 18; in the Canton of Neuchatel, 189; in Sweden, 461; at Oban, 561
East Anglia, Geology of, 130
Eaton (H. S.), Greenwich as a Meteorological Observatory, 489
Echidna, a new Species of, 66
Eclipses: the Nineveh of B.C. 763, 65; Sir G. B. Airy on Ancient Solar, 115; Ancient Solar, 186; Solar, of Stuklastad, 1030, 206; Solar, of 1567, 342; Total Solar, 457
Edinburgh: Royal Society, 109, 192; Royal Physical Society, 422; Observatory, Deep Soil Thermometers at, 521
Edward (Thomas, A.L.S.), Life of, by Samuel Smiles, 349, 439; Testimonial to, 479
Edwardes (Rev. D.), Holly-Berries, 295
Edwards' Butterflies of America, 70
Eel, the, 324; Electric, 414, 501
Effendi (Emin), Travels of, in Africa, 169
Egypt, Educational and Scientific Institutions in, 364
Electric Motor Pendulum, Dr. Paget Higgs, 98
Electric Light in Paris, 284
Electrical Phenomenon, Prof. George Forbes, 450
Electricity: Influence of, on certain Spectra, 70; Cumming's Introduction to the Theory of, 526, 549

Electro-Capillary Phenomena, Dr. Paget Higg, 7

NATURE

A WEEKLY ILLUSTRATED JOURNAL OF SCIENCE

"To the solid ground
Of Nature trusts the mind which builds for aye."—WORDSWORTH

THURSDAY, NOVEMBER 2, 1876

THE ARCTIC EXPEDITION

IT is pleasing to be able to begin our fifteenth volume with congratulations to the officers and men of a British Arctic Expedition on their safe return. On another page we give a summary of the results obtained so far as these can yet be known. It will be seen that substantial additions have been made to our knowledge in many directions, and that the expedition must be pronounced a success. True, the Pole has not been reached, but this, in the consideration of all but the mere lovers of sensation, is a small matter; our explorers hav done the next best thing to reaching it, they have proved that the Pole was impracticable this year from quarter whence success was most to be expected. It is evident from the few hints which have already been published, that when all the tale is told, it will be quite as thrilling, and full of dangers and bravery, as any previous narrative of Arctic exploration. So far as the conduct of the expedition is concerned, it seems to have been all that could be wished; the original programme was, on the whole, closely stuck to, and the desperately hard and dangerous work was done in the most systematic and economical way at present possible. Everybody seems to have behaved admirably; there seems to have been no fault whatever to find with anyone; and so much has Capt. Nares endeared himself to officers and men, that he earned for himself the common title of "the father" of the expedition.

It was hardly to be expected that an expedition, on such an errand, and with such unprecedented dangers to face as this one has had, would return without casualties; they have left four of their comrades behind them. Of these one only died as the result of frost bite, the three others succumbing to that most dreaded of all Arctic foes, scurvy. No similar expedition ever left any country so well provided with everything that could be thought of conducive to sustenance and protection. There was an ample supply of fresh provisions of all kinds, sufficient staff, and all precautions were evidently taken throughout the long winter to keep everyone employed, and cheerful, and duly exercised. Yet, in all the sledge-parties, scurvy broke out with a virulence and to an extent not experienced, we believe, in any recent Arctic expedition. The cause of this outbreak will no doubt give much food for thought for some time to come, some thinking that the unusual length and intensity of the darkness may have had something to do with it. The darkness seems to have been much more intense, and certainly was longer-continued than ever before experienced, and such a condition, not to mention its effect on the spirits of the must necessarily, one would think, exercise some deleterious physical influence on the body. This is a point deserving of careful consideration; meantime we nnot but admire the way in which officers and men of these sledge-parties did their work in spite of physical and terrible suffering; it would, however, have been surprising had the record been otherwise.

No men could have exerted themselves more to accomplish the popular, but really minor, object of their expedition, and none could have been more honourably baffled. The ice was met with off Cape Sabine in 41′ N., and from that time till the *Alert* was compelled to take up her quarters in 82° 27′, it was a constant battle with ice of a thickness never before met with. The ice was from 100 to 150 and even 200 feet thick, resembling more a pell-mell assemblage of icebergs than the usual floes; to have been nipped between the masses of such ice would certainly have been fatal. Commander Markham in his daring attempt to carry out the instructions of the expedition by penetrating as far to the north as possible, found the ice piled in such rough and hilly hummocks that progress was only possible at the rate of a mile a day, and he wisely returned after reaching 83° 20′ N., the highest authentic latitude yet attained.

Capt. Parry's long and weary journey, which reminds one to a certain extent of that of Commander Markham, was only as far as 82° 45′; the Austro-Hungarian expedition of 1872-4 reached 82° 5′, though they saw as far as 83°; while Hall with the *Polaris* sailed without let or hindrance in 1872 over the same ground as the *Alert* and *Discovery* for 700 miles to 82° 16′ N. in the short space of one week.

Any such frightful ice-barrier as that reported, and, let us add, admirably photographed, by our expedition was not seen by Hall and his men; and indeed it has been stated that had it not been for the scruples of the second in command, Buddington, Hall would have pushed still further northwards, all on board, except Buddington, who had no heart in the work, agreeing that the undertaking was perfectly practicable. Meyer, in his evidence before the U.S. Commission, declared that if 82° 16′ could have been passed, there was nothing to hinder a ship reaching 85° or 86° " or even farther. Had poor Hall not met with an untimely death, the attempt would certainly have been made in the following summer. This terrible ice-barrier, then, before which our expedition has wisely returned, does not appear to be a constant phenomenon so far south, for Hall's observations have been generally accepted as perfectly trustworthy. May there not have been some cause at work in the high north to push the thick-ribbed ice south to the northern entrance of Robeson Channel? This seems to have been an unusually severe season in the north; icebergs were met with in abundance a week or two ago far south in the Atlantic, and last week we reported the wreck of a whole fleet of whalers in the Behring Straits region. If the latter casualty has been produced by ice, it would seem to show that some cause has been at work this season to render it unusually unfavourable for Arctic work. It is perhaps worth noting here, at least, that 1871 was a maximum, while 1876 is a minimum, sun-spot year. The temperature was undoubtedly the coldest on record, neither the *Polaris* nor the Austro-Hungarian expedition experiencing anything like it, namely, 104° of frost. There was no stint of animal life in the region in which the *Polaris* wintered, and as far north as the expedition penetrated, it was observed, while the Austro-Hungarian expedition found the cliffs swarming with life at their farthest north point. The dearth of animal life is a noticeable feature in the results of our expedition; it ceased altogether at a short distance to the north of the *Alert's* quarters. The prevailing wind during the sojourn of the *Polaris* was from the north-east; this year it is stated scarcely any easterly wind was noticed, but a strong current and drift set constantly in from the west along the north coast of America. We mention these points simply to suggest that the conditions met with by our gallant expedition can hardly without further observations be regarded as the normal ones. Round the Pole doubtless there must be a permanent barrier of impenetrable floe-bergs, for it would be ridiculous to suppose that 150 feet thick ice of thousands of square miles in extent is melted and re-formed every year. But is it possible that usually this barrier lies further north than our expedition found it?

As to positive discoveries, an unprecedentedly rich collection of observations in all departments have been obtained. It will be seen from our map that positive additions have been made to Arctic geography. With the exception of Hayes Inlet, all the coast from Cape Farewell to the northern end of Robeson Channel is now laid down, and considerable advances have been made west along the American, and east along the North Greenland coast, in the former case to 86° 30′ W., and in the latter to 48° 33′ W. President Land does not exist, no land having been seen north of Cape Columbia in 83° 7′ N. It was a pity that Petermann Fjord was blocked up with ice, otherwise it might have been ascertained whether or not it divides Greenland in two, as has been conjectured. There is little doubt, at any rate, that Greenland is an island, and that it does not extend right across to Wrangell Land as Petermann conjectured. For the more important scientific observations we must wait some little time, but we have reason to believe they are abundant and of the highest value. The drift of the current along the North American coast it will be seen, is from the west, and it is possible it may come right across from Behring Straits. A magnificen series of tidal observations has been obtained, entirely confirmatory of the conclusions that Bessels came to, viz. that the tides in the north of Smith's Sound come from the Pacific. It would be interesting now to know what lies between Parry Islands and the newly discovered coast, and whether currents have an unobstructed passage from Behring Straits across the Polar Sea. The magnetic observations entirely endorse the theory on which the charts have been constructed; and had it not been for a change of officers and an accident to the clock, the pendulum observations for determining the figure of the earth would have been completed and of the greatest interest. Capt. Feilden, the naturalist, whose exertions are beyond all praise, obtained admirable results in his department.

We may be permitted to say that we think Capt. Nares has acted gracefully and generously in his selection of names for the lands discovered; the most northern point discovered now bears the name of Cape Columbia. It was in keeping with this disposition to recognise America's claims to remembrance that Capt. Nares paid a deserved tribute to the brave Hall by affixing to his no longer lonely grave a brass tablet containing a suitable inscription.

Altogether we have every reason to be satisfied with the conduct and results of the expedition, and thankful that these results have been obtained with so little loss. It might have been otherwise, for the *Discovery* was within a minute of being crushed by an iceberg, and had it not been for an accident to the *Alert's* screw, she would certainly have pushed further north and got into a position from which it would have been impossible to extricate her. Many lessons with regard to future Arctic work are to be learned from the experiences of this latest expedition. We would also remind our readers of the plan advocated by Weyprecht, and recommended by a German Government Commission, to establish at suitable points all round the Polar region a series of permanent stations from which the Arctic citadel can be slowly but surely sapped. The recommendations of the German Government Commission we consider so important, that although we published them at the time, we think it appropriate to reproduce them here in the present connection, and the admirable scientific spirit in which the subject is approached is worthy of note.

"1. The exploration of the Arctic regions is of great importance for all branches of science. The Commission recommends for such exploration the establishment of fixed observing stations. From the principal station, and supported by it, are to be made exploring expeditions by sea and by land.

"2. The Commission is of opinion that the region which should be explored by organised German Arctic explorers, is the great inlet to the higher Arctic regions situated between the eastern shore of Greenland and the western shore of Spitzbergen.

> "Considering the results of the second German Arctic expedition, a principal station should be established on the eastern shore of Greenland, and, at least, *two* secondary stations, fitted out for *permanent* investigation of different scientific questions, at Jan Mayen and on the western shore of Spitzbergen. For certain researches the principal station should establish temporary stations.

"3. It appears very desirable, and, so far as scientific preparations are concerned, possible, to commence these Arctic explorations in the year 1877.

"4. The Commission is convinced that an exploration of the Arctic regions, based on such principles, will furnish valuable results, even if limited to the region between Greenland and Spitzbergen; but it is also of opinion than an exhaustive solution of the problems to be solved can only be expected when the exploration is extended over the whole Arctic zone, and when other countries take their share in the undertaking.

"The Commission recommends, therefore, that the principles adopted for the German undertaking should be communicated to the Governments of the States which take interest in Arctic inquiry, in order to establish, if possible, a complete circle of observing stations in the Arctic zones."

But to come to any final decision on the subject at present, as have some of the daily papers, is premature, more especially as we have only mere hints of the work of the latest expedition before us. It is evident, however, that three courses are open to us: we may rest on our oars and comfort ourselves with the belief that no more can be done; we may make another dash, blind to a certain extent it must be with our present knowledge; or, accepting the recommendation of the German Commission, a united and continuous sap may be commenced. But in order to come to a wise decision, men of science must long ponder over the enormous mass of new facts collected by the expedition, and not until this has been done can any opinion worth the stating be possibly arrived at.

Here we would have ended had it not been for the lamentable tone assumed by our leading newspaper in an article on the expedition in Tuesday's issue. It will be remembered that from the first, for some unaccountable reason, the *Times* set its face against the expedition, and prophesied that no good could come of it; now it utters a lonely shout of triumph at the supposed success of its prophecy. For the *Times* appears to be so ill-informed as to believe that the main, if not the sole, object of the expedition was to reach the Pole; if it failed in doing this, then, in the eyes of the *Times*, it was a complete failure. But this is sheer ignorance, real or assumed, on the part of the *Times*; for no informed person ever dreamt that the only object of the well-equipped expedition was to gratify unintelligent curiosity and craving after sensation. The printed instructions of the expedition were essentially: "Reach the Pole if you can, but at any rate, in the light of the latest scientific knowledge, make all possible observations on the multifarious phenomena which can be seen to advantage alone in the Arctic regions." These instructions have been faithfully carried out and with complete success. Every [illegible] made to reach the Pole, and when the results are published it will be seen that no expedition ever brought home a richer harvest. Whether these results are worth the suffering and the sacrifice of life which the expedition experienced, is a question which will be answered in accordance with one's idea of what is worth running the risk of life for. In spite of the scream of the *Times*, and although no new market has been opened, the people of this country will simply feel proud, and be ennobled by the thought, that the latest deed of heroism has been done by Englishmen—that "the ancient spirit is not dead."

The nation desired the expedition, scientific bodies and scientific men counselled it and worked for it, Government, only after long consideration, willing and liberally granted funds; and out of the volunteers, officers and men, who, well knowing all the risks that would be run, eagerly offered themselves for the service, a dozen similar expeditions could have been equipped. Under these circumstances the *Times'* article is simply an impertinence.

SCHIMPER'S "MOSSES OF EUROPE"

Synopsis Muscorum Europæorum. Auctore W. P. Schimper. Vol. I.—Introductio, pp. 130. Vol. II.—Specierum descriptio, pp. 886. Edit. 2. Stuttgartiæ, 1876. (London: Williams and Norgate.)

THIS long expected work has at last made its appearance, and all students of bryology will be grateful to possess such a vast storehouse of carefully arranged descriptive matter to help them in the determination of species; no easy task at any time, and sometimes one of difficulty and trouble even to an expert.

The first edition appeared in 1860, and we must frankly admit that we experienced some feelings of disappointment, on finding that almost the entire nomenclature and arrangement are identical with those of that edition; nay, in some respects we must look upon the classification as retrograde, for while in his classical work on the Sphagnaceæ, Prof. Schimper strongly insists on the elevation of this family to the rank of a class equivalent to those of Mosses and Hepaticæ, we here find him placing them along with *Andreæa* and *Archidium*, as an appendage to the mosses, under the title of BRYINÆ ANOMALÆ; surely a most unphilosophical mode of dealing with them, since the three genera have nothing else in common but the large saccate calyptra, which had already led Hampe to separate them as a section—*Saccomitria.*

The Cleistocarpous order heads the series, though the author half apologises for still retaining it "as being convenient for beginners, and because the position of some of them among the Stegocarpi is uncertain." Several of our best bryologists, however, have long felt that the solitary character of possessing a capsule without a separable lid, is not sufficient to outweigh all other points of structure and habit, especially when it also necessitates keeping up two parallel series of forms in widely separated families, *e.g.*, *Phascaceæ* and *Pottiaceæ.* We would venture to differ from our author, and consider that *Archidium* is a near ally of *Pleuridium*, and that the absence of a columella is not so momentous a character as to require the separation of these genera to the extreme ends of the system; while *Andreæa* as to its vegetative organs is essentially Grimmiaceous, but in its fruit standing apart and thus representing a most distinct natural family, imitating as it were the Hepaticæ by its quadrifid capsule, but not having any real affinity with that group.

About 200 new species are described in the present edition, many of them only known in a barren state, and in several instances misgivings are expressed by the author as to their stability. We may glance at some of these *en passant*. *Ephemerum* has one new species, *E.* , and we surmise our Sussex plant (*E. inter-* Wils., *E. tenuinerve*, Lindb.) is also distinct. The *Ephemeraceæ* really seem to merit the rank of a natural family rather allied to *Trichostomaceæ* than to *Funariaceæ*, for which the diminutive size, permanent protonema, and leaf structure would supply the chief characters.

In *Weissiaceæ* we find *Anœctangium*, a genus which has exercised the minds of most bryologists as to its systematic position, but which perhaps is as happily settled here as is possible. *Gyroweisia*, and *Rhabdoweisia*, standing as sections of *Weisia* in the previous edition, are now raised to the rank of genera. In *Dicranaceæ* we have also a new genus—*Metzleria*—which appears to be very close to *Dicranodontium*, and *Campylopus* now includes twelve species, while those of *Fissidens* number no less than nineteen. *Leptotrichum*, Hampe, is still retained as a genus, though its author has himself replaced it by the much older name, *Ditrichum*, Timm.

Didymodon and *Trichostomum* receive considerable additions, chiefly, however, only known in a barren state, as is also the genus *Geheebia*, established to receive *Tortula gigantea*.

We pass next to the great genus we find no less than forty-two species; so uniform are these in habit and foliage, that they have hitherto proved a most troublesome group to deal with, nor do we find that the nine sections into which it is divided help us readily to determine the species. In no genus of mosses do we require so full a series of specimens, for we must have the capsule with its calyptra, and with and without the lid, in order satisfactorily to determine them, and we fear that more species have been established than will eventually prove tenable.

Bryum is another genus receiving a large accession of species—no less than thirty-four new ones—and *Zieria* is still maintained, though used long ago by Sir J. E. Smith for a genus of *Rutaceæ*, and therefore altered by Prof. Lindberg to *Plagiobryum*, which must certainly be adopted. In the Addenda we also find a new genus, *Merceya*, founded on the *Eucalypta ligulata* of Spruce, but strictly we should say that this name must give place to *Scopelophila*, Mitten. Another new genus, *Anacolia*, is also established for *Glyphocarpus Webbii*.

Among Pleurocarpous mosses, *Myurella Careyana* does not find a place, although recorded as found in Europe. *Thuidium decipiens*, De Not., the author states he has not seen, yet it was distributed in Rabenhorst's Bryotheca under both No. 1,141 and 1,182. It has no relation to the genus *Thuyidium*, is erroneously described as monoicous, and indeed can only be regarded as one of the many forms of *Hypnum commutatum*. Of the great tribe *Hypneæ* thirty-six new species are described.

In the BRYINÆ ANOMALÆ we find *Sphagnum* now numbering twenty species, grouped in six sections according to Schliephacke's arrangement. These we fancy will have to be somewhat reduced, as it now appears to be certain that in this family at least, a dioicous and monoicous condition of the inflorescence may occur in the same species.

Neglect of the work of other writers and especially of papers in the various botanical journals of this and other countries is the principal shortcoming of the work before us, and probably the author has not had time properly to consult them; in every other respect the Synopsis maintains the high character it had already acquired, for no description of species could be more accurate and painstaking, while the paper and printing are superior to the ordinary run of foreign books.

It will thus be seen that Schimper's Synopsis mus still continue to be the standard work on the mosses of Europe, and fitly comes to us from an author whose name has been identified with the study of these interesting plants for the past forty

OUR BOOK SHELF

Outlines of Practical Histology. By William Rutherford, M.D., F.R.S. Second Edition. (J. and A. Churchill, 1876.)

WHEN, a year ago, we reviewed this work upon its first appearance, it consisted of but seventy-two pages, and contained four illustrations; the second edition occupies very nearly two hundred pages, and is illustrated with sixty-three woodcuts. The enlargement gives the author an opportunity of entering with considerably greater detail into his subject, and he is able to introduce much new matter. Among the most important additions we may mention a chapter on the optical principles upon which the microscope is constructed, including immersion lenses, and an instrument manufactured by Mr. Swift of London, which is apparently as good as those of continental celebrity. The histological sections may be said, practically, to be re-written, for to almost every one is added matter of great value, essential to all but the merest commencer. Among these we notice paragraphs upon the effects of gases on the blood, the enumeration of the discs, the "prickle" cells of the epidermis, lymphatics of the diaphragm, coverings of hair, structure of the retina and of the cerebral convolutions. In the fourth part of the work, which is devoted to general considerations regarding histological methods, the application of vapours and gases to tissues is explained, as are the hot stage for the microscope, with its heating apparatus and the moist chamber of Dallinger and Drysdale. The author's microtome is figured, as is the apparatus necessary for injecting tissues by the pressure-bottle. All the figures are excellently drawn, and very lucid, and so greatly has the book increased in value, instructive as it was before, that we feel quite justified in recommending those who possess the first edition to purchase the second, and those who are studying the first principles of practical histology to obtain it without fail.

A Study of the Rhætic Strata of the Val di Ledro in the Southern Tyrol. By T. Nelson Dale, jun., Member of the Geological Society of France. Pp. 69, with and Sections. (Paterson, New Jersey, 1876.)

ON the western side of the Lago di Garda is situated tract of Secondary rocks which has been comparativ little explored by geologists. Lying as it does exactly upon the Austro-Italian frontier, this area has neither described by Stoppani and the Italian geologists, nor has it received full justice from the officers of the Vienna *geologische Reichsanstalt;* and under these circumstances Prof. Zittel of Munich has pointed it out to the author of the present paper as a promising field of study. Mr. Dale's work will certainly be of considerable use to future explorers of the district, though not carried out in sufficient detail to warrant, in his own case, any very important generalisations. Indeed, the memoir consists almost wholly of transcriptions of notes and rough drawings of sections relating to a number of different localities which are indicated by reference to a key-map. The author's general conclusions, so far as they go, are shown in a very clear and useful table, from which it appears that at this point of the Alps, the Jurassic and Rhætic strata (including in the former the Tithonian) have a united thickness of from 6,000 to 7,000 feet. Vast as is the estimate, no one acquainted with this or the surrounding districts will be inclined to regard it as excessive.

Mr. Dale has evidently made good use of his opportunities, so far as they have gone, and has given us in this memoir the results of a piece of well-directed observation. We hope to have further details from his pen concerning the same interesting region. The list of *errata*, which is rather long for a memoir of the proportions of the present, does not by any means exhaust the whole of the printer's errors. We are tempted to fear that Mr. Dale is not sufficiently careful in keeping so distinct from one another, as behoves a working geologist, his notes relating to various subjects; for, by some strange chance a stray page of a sermon seems to have fallen into the hands of the compositor and to have been set up by him at the end of the author's geological notes.

J. W. J.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*]

"Geographical Distribution of Animals"

I FIND that Mr. Wallace in his new work on the "Geographical Distribution of Animals" when stating the limits of his Ceylon sub-region (vol. i. p. 327), gives among mammals the genus *Tupaia* and among birds "a species of *Myiophonus*, whose nearest ally is in Java" as characteristic of that sub-region. Further, in the tabular statement (vol. ii. p. 187), *Tupaia* is altogether omitted from the Indian sub-region.

It is not my intention to enter here into the general question of the divisions of the oriental region which Mr. Wallace has adopted. The subject has I know been undertaken by at least one well-known Indian naturalist. My object at present is simply to record the fact that I have found both *Tupaia Elliotti* and *Myiophonus Horsfieldi* ranging together far to the north of the limits given by Mr. Wallace for his Ceylon sub-region.

Tupaia I first met with at an elevation of about 1,500 feet in the Sutpuru Hills, near the *Pachmari* plateau in the Central Provinces (P.I.A.S.B., April, 1874), lat. 22° 20′. Subsequently I found it in Sambalpur, which is the most eastern district of the Central Provinces (lat. 21° 30′). But the former does not even give its extreme northern limit as it has been found in the Kurrucpur hills of the Monghyr district (lat. 25°).

Myiophonus Horsfieldi I first shot in Sirguja—a native state in Western Bengal (lat. 23°). Afterwards in the Sutpurus, where it occurred with *Tupaia* as above, and finally I obtained it also in Sambalpur, where it was found at elevations under 1,000 feet above the sea. Still further north it has been obtained at Mount Aboo ("Stray Feathers," vol. iii. p. 469), lat. 25°.

Myiophonus is, it is true, included in Mr. Wallace's list of Oriental genera in Central India, but its special employment as a characteristic form of the Ceylon sub-region seems scarcely compatible with a knowledge of its now ascertained wide range through continental India.

During the ensuing field season I expect to be engaged in the geological examination of one of the wildest and least known parts of India—the area between the Godaveri and Mahanudi Rivers. I have great hopes of discovering there further facts regarding the range of species whose limits are now only imperfectly known. In the meantime I may state that during the present year I have shot *Hurpactes fasciatus* in Sambalpur, thus confirming the late Col. Tukell's statement of its occurrence in the same general tract of country. The above allusion to *Tupaia* leads me on to record here that I have met with two other species of the genus.

During an ornithological tour which was made in 1873 by a party of which I was a member—through the islands of the Andaman and Nicobar groups—we obtained a species of *Tupaia* on the Island of Preparis. Our specimen appears to be identical with *T. Peguensis*, which occurs from Pegu to Sikkim. On the Great Nicobar we shot a specimen of the species described in the Novara account as *Nicobariensis*, and considered then to be worthy of generic distinction.

In Preparis, it may be added, we also shot a small grey squirrel which is allied to if not identical with *S. Assamensis.* These, with a monkey (*M. carbonarius?*), pigs, and probably rats and bats, constituted so far as we could ascertain the mammal fauna of the island.

Preparis I should perhaps explain is the most northern of the Andaman group lying between Cape Negrais and the Cocos.

Mr. Wallace has I observe included the Nicobar Islands in the Malayan sub-region and the Andamans in the Indo-Chinese. This separation of the two groups is, I believe, fully justified by the facts.

Some years ago when working at the avifauna of these islands (J.A.S.B., 1872, p. 274), while recognising the fact of a number of species being common to both groups, I could not resist a conviction as to the existence of a strong Malayan stamp upon the birds which are peculiar to the Nicobars.

In conclusion Mr. Wallace's magnificent work needs no praise from me; but as a field worker and observer I may perhaps venture here to offer my thanks for the valuable mine of information which it affords.

V. BALL,
Geological Survey of India

Calcutta, September 28

European Polygalas

IN view of a monograph of the order Polygalaceæ which I have in preparation, may I make use of your columns to say that I should be greatly obliged to any correspondents who can send me specimens of any of the less common European *Polygalas*, especially *P. exilis*, *monspeliaca*, *microphylla*, *saxatilis*, *Preslii*, *nicæensis*, *flavescens*, *rosea*, *sibirica*, *supina*, *venulosa*, *anatolica*, or any well-marked varieties. I shall be glad to offer in exchange specimens of some of the rarer British plants.

ALFRED W. BENNETT

6, Park Village, East, Regent's
Park, London, October 28

The Solidity of the Earth

IN his opening address to the Mathematical and Physical Section of the British Association, Sir William Thomson affirmed "with almost perfect certainty, that, whatever may be the relative densities of rock, solid and melted, or at about the temperature of liquefaction, it is, I think, quite certain that cold solid rock is denser than hot melted rock; and no possible degree of rigidity in the crust could prevent it from breaking in pieces and sinking wholly below the liquid lava," and that "this process must go on until the sunk portions of the crust build up from the bottom a sufficiently close-ribbed skeleton or frame, to allow fresh incrustations to remain bridging across the now small areas of lava, pools, or lakes" (NATURE, vol. xiv. p. 429).

This would doubtless be the case if the material of the earth were chemically homogeneous or of equal specific gravity throughout, and if it were chemically inert in reference to its superficial or atmospheric surroundings. But such is not the case. All we know of the earth shows that it is composed of materials of varying specific gravities, and that the range of this variation exceeds that which is due to the difference between the theoretical internal heat of the earth and its actual surface temperature.

We know by direct experiment that these materials, when fused together, arrange themselves according to their specific gravities, with the slight modification due to their mutual diffusibilities. If we take a mixture of the solid elements of which the earth, so far as we know it, is composed, fuse them, and leave them exposed to atmospheric action, what will occur?

The heavy metals will sink, the heaviest to the bottom, the lighter metals (*i.e.* those we call the metals of the earths, because they form the basis of the earth's crust) will rise along with the silicon, &c., to the surface; these and the silicon will oxidise and combine, forming silicates, and with a sufficient supply of "reason to believe that this is the first specimen of a wild Capercailzie which has been shot in Northumberland in the memory of man."

Probably the writer's glee was somewhat chilled by the appearance in the same paper of an indignant letter from the Earl of Ravensworth, stating that the bird was reared in his park at Eslington from eggs sent from the Highlands, in the hope of naturalising the species in our country; the bird had strayed from its home.

All naturalists—and especially such as know this noble bird in its northern home—must hope that Lord Ravensworth will not be discouraged by this mishap, nor by others like it, but that he will persevere in his experiment. Eslington Park is situated in the valley of the Aln, near the foot of the Cheviots. Perhaps this is not the best part of the country in which to rear the birds, as, although not devoid of timber, the woodland there is scarcely that most suited to the Capercailzie. Pine woods on rocky ground are probably the best. Not far from Eslington, and partly on the Ravensworth estates, there is a superb piece of woodland and crag. Thrunton Crags, and the adjoining crags of Callaly, are very little known except to those who live near them, for they are out of the usual tourists' routes. But in all the county we do not know a district better worth a visit, nor one which so closely resembles the fir-clad mountain sides of southern Norway. The rocks are craggy sandstones, whilst those of Norway are mostly bosses of schists, and there is none of the water which gives such a charm to Norwegian scenery, but, in spite of these differences, the other resemblances point out this as the Capercailzie's fitting home.

A wide area of high sandstone moorland stretches through Northumberland, attaining a height of over 1,400 feet at Simonside, near Rothbury, and approaching 1,000 feet in other places. This runs to the west of Alnwick, and thence north-west to Chillingham and away towards the Tweed. Another similar district branches from that of Simonside and spreads over a wide area around Harbottle, and between the Coquet and the Reed. Of the first-named range the crags of Thrunton and Callaly form conspicuous features. Only a small part of this range is wooded. It is much to be wished, for the sake of the springs and streams, that plantations were more numerous; and for many reasons, artistic and others, we could wish the same. In such parts of these wild hills as fir plantations occur, the Capercailzie should do well; and, as plantations increase, we might hope that the birds would here find a permanent home. Besides the crags of Thrunton and Callaly we may note, as districts especially well suited to them, the fir woods of Harbottle; parts of the Duke of Northumberland's extensive park at Alnwick; and the wild forest-like park at Chillingham, the home of the far-famed "wild cattle." In years to come, when the plantations increase, Sir W. Armstrong's grounds at Cragside, near Rothbury, will afford the birds a shelter. Here, amidst a profusion of sub-Alpine plants, the Capercailzie should be quite at home. W. TOPLEY

NEWTON ON FORCE

MANY English mathematicians are in the habit not only of using the word "force" in a certain technical sense—briefly, as cause of change of motion—but of regarding all other senses as loose and inaccurate. Of late years there has been an increasing tendency, largely due to Sir W. Thomson and Prof. Tait, to return to the methods of expressing dynamical principles used by Newton; so that at the present time his statement of the laws of motion is adopted to the exclusion of others which had usurped its place. This return to Newton has led to a very prevalent notion that for all the statements of fundamental dynamical principles current in modern English mathematical literature, we have his authority, and in particular for the above-mentioned restriction of the use of the word "force." As the authority of Newton seems to me to be here claimed without warrant, and as Newton's conception of force cannot be without interest, I propose to examine as briefly as possible what this conception was. In doing so I shall assume that the English word "force" is the equivalent of Newton's Latin word *vis*.

Newton commences the Principia with eight definitions, among which are definitions of the intrinsic force of matter (*vis insita* or *vis inertiæ*), impressed force, and centripetal force; he then proceeds to state and explain the laws of motion. From the chapters on the definitions and the laws of motion, we are able to infer with much probability the sense in which the word "force" is used. To show this it will only be necessary to translate a few extracts.

"Def. III.—*The intrinsic force of matter* is its power of resistance, by which every body, as far as depends on itself, persists in its state either of rest or of uniform rectilinear motion."

"Def. IV.—*An impressed force* is an action exerted on a body towards changing its state either of rest or of uniform rectilinear motion."

"Def. V.—*A centripetal force* is one by which bodies are pulled, pushed, or in any way tend from all parts towards any point as a centre."

"Just as in cases of impact and rebound bodies are equipollent whose velocities are reciprocally as their intrinsic forces; so in moving mechanical instruments agents are equipollent, and mutually support each other by their contrary efforts, whose velocities, estimated in the direction of the forces, are reciprocally as the forces." (Scholium to the Laws of Motion.) In the latter part of this quotation the word "forces" is used in the sense of impressed forces as defined by Def. IV.

One more quotation must be made; it is from Newton's comment on Def. III.: "—but a body exerts this force [*vis inertiæ*] only while a change is being made in its state by another force impressed on it."

In the quotation from the Scholium, Newton is considering two cases in which bodies are to be moved; in one the power of resisting the motion arises from the intrinsic force of the body (or its *vis inertiæ*), in the other from the impressed force; in each case he seeks a measure of the effort required to move the bodies. Newton argues that, in the first case, this is to be measured by the intrinsic force and velocity conjointly, and in the second by the impressed force and [virtual] velocity conjointly; implying that, in the first case, to give a body a certain velocity is equivalent to giving a body of twice its intrinsic force half that velocity; and in the second case—to take an example—that to lift a body vertically at a certain rate is equivalent to lifting a body of twice its weight at half the rate.

In this Scholium, in the case both of intrinsic force and of impressed force, the word "force" indicates some power of resistance to change of state; a general power due to the intrinsic force, and a special power due to the impressed force. And throughout it will be found that Newton's use of the word *in its most general sense* indicates a power of resistance, which professed metaphysicians are not alone in attributing to matter as essential to the conception of it. This most general sense of the word does not prevent Newton using it in any one of its special senses, and in particular very frequently for *impressed* force, where no confusion is likely to arise; but his language is very far from sanctioning the dictum that this is the sense and the *only* sense in which the word "force" may be used.

It is painful to reflect that Newton, great as he undoubtedly was, does not seem to have been sufficiently advanced to doubt whether there is such a *thing* as force, nor to have had a proper sense of the heinousness of his conduct in writing of accelerative force, motive force, and—worst of all—centrifugal force. P. T. MAIN

PRINCIPLES OF TIME-MEASURING APPARATUS[1]

IV.

THE earliest watches were constructed, so far as the escapement and balance were concerned, upon exactly the same plan as the clock from Dover Castle, and in this condition they must have perpetually remained (useless as time-measurers), but for the invention of the balance-spring (sometimes called the pendulum-spring, on account of the uniformity it imparts) by Dr. Hooke.

This spring bears the same relation to the balance which gravity does to the pendulum. Everybody, I presume, knows the form it usually takes in watches; and in chronometers it is coiled up around an imaginary cylinder. This spring (as in the case of the pendulum) absorbs the energy of the impulse, and when the balance has reached the limit of its swing, redelivers to it all it has received. A watch is regulated by shortening or lengthening the balance-spring, which makes it more or less rigid.

Watches and chronometers vary their time to a much greater extent upon any change of temperature than clocks do. For instance, if we regulate a chronometer without any compensating arrangement, with a balance-spring of steel, to go right at a temperature of 32 deg., when we raise the temperature to 100 deg. it will lose 6 minutes 25 seconds a day, whereas a clock with an ordinary steel rod pendulum would barely lose 20 seconds for the same change. This great difference is owing to the alteration in elasticity of the balance-spring (the effect really being the same as if, with reference to the pendulum, we could reduce the force of gravity).

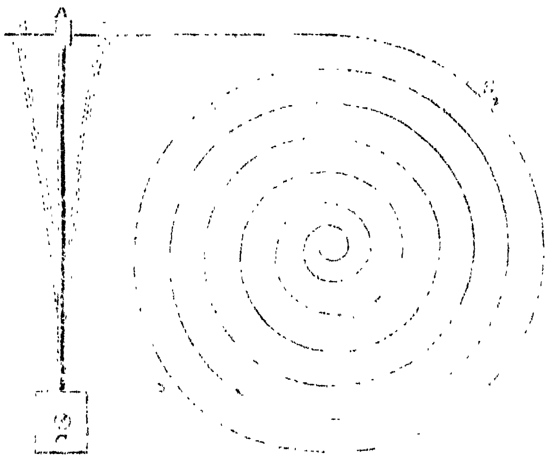

FIG. 19.

Different materials are in this respect differently affected. Whereas a chronometer with a spring of steel will lose 6 minutes 25 seconds a day for 68 deg. rise in temperature, one with a gold spring would lose 8 minutes 4 seconds; a palladium spring would lose 2 minutes 31 seconds; a glass[2] spring would lose 40 seconds. On account of the large amount of compensation required, quite a different plan has to be employed to that made use of in clocks.

Suppose I take two thin strips of brass and steel, and fasten them rigidly together (the best plan is to pour the melted brass upon the steel), what will happen when there is any change of temperature? Imagine the temperature to rise, both expand, but the brass more than the steel, and how it manages this, being rigidly fastened to it, is by bending round the steel into a curve, of which *it* (the brass) is upon the *outside*.

Fig. 19 represents the first form of compensation applied to watches. C A is our compound bar (the steel, shaded black, being nearest the spiral), the extremity of which carries two pins applied to the balance-spring as the ordinary regulator.

When the temperature rises the brass expands and bends round the steel, shortening the balance-spring, and thus compensating for its loss of elasticity due to the rise in temperature. The reverse action takes place when the temperature falls.

The plan adopted now-a-days is the compensation-balance (see Fig. 20). The rims, R_1R_2, are formed of two strips of brass and steel, the brass being upon the outside. When the temperature rises, the brass expands more, and bends in the rims, carrying the weights W towards the axis of motion a sufficient distance to compensate for the loss of time due to the loss of the spring's elasticity.

As you see, the action of the compensation may be readily increased by shifting the weights nearer to the ends of the rims.

Where a chronometer is exposed to very wide ranges of temperature, there is another error (called the secondary error) introduced. If, for example, we take a chronometer with such a balance as just described, and so adjust the compensation-weights that it shall go right at a temperature of 66 deg. and 32 deg., we shall find that when we expose the chronometer to a temperature of 100 deg. it will lose about four seconds a day; and we cannot correct it, for if we advance the compensation-weights along the rims to increase their action in the heat, we shall also increase it in the cold, and then the chronometer will lose in that direction. The best we could do would be so to adjust the weights as to make the chronometer lose two seconds a day in the heat, and two seconds a day in the cold.

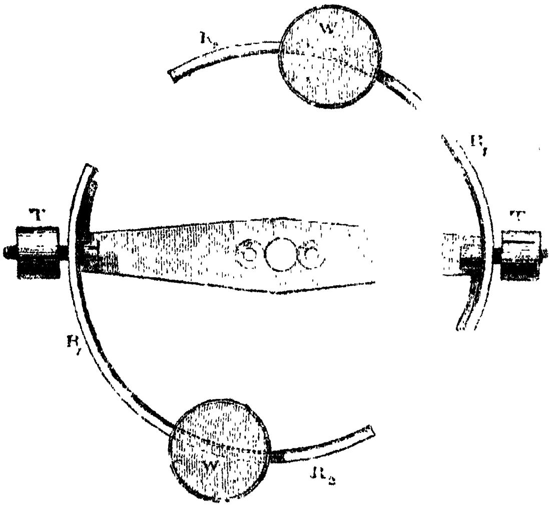

FIG. 20.

The cause of this error is that the time of the swing of a balance depends not directly upon the distance of its weights from the axis of motion, but upon the square of that distance; and it therefore requires a greater amount of motion inwards to produce the same effect as any given motion outwards.

The following is one of the plans adopted for the correction of this error (see Fig. 21):—

F B is a flat bar composed of brass and steel fastened together, the brass being beneath. L L are two loops also formed of brass and steel, the brass being inside. The compensation weights, W W, are mounted upon

---

by Mr. H. Dent Gardner, at the Loan Collection, South
ded from vol. xiv. p. 575.
as the invention of the late Fredk. Dent.

two rods, R R, fastened upright upon the extremities of the loops.

When the temperature rises, the flat bar bends upwards, and tilts in the loops and the weights at their extremities. But at the same time the loops open a little, and as they are pointed towards the axis of motion, A A, advance the compensation weights a little further in upon their own account. Thus the action of the main bar is increased in the heat. In the cold, the main bar bends downwards, and tilts out the weights, but in this case the loops close, and as they are now pointed away from the axis of motion, by doing so, *bring back* the weights a little. Thus the action of the balance is reduced in the cold. The secondary error is in this manner corrected.

Balance-springs have this very important property, that you are able to isochronise them, that is, so adjust them that the balance shall perform long and short arcs of vibration in the same time. The rule for doing this is simple, though exceedingly difficult of execution upon account of the minuteness of the operation; if the chronometer gains in the short vibrations, you shorten the spring, and if it gains in the long vibrations, you lengthen it. The best plan is to leave it gaining a trifle in the short vibrations, for the reason I pointed out to you when discussing the circular error in pendulums. A chronometer gaining 3 or 4 seconds a day in the short vibrations will also be compensated against changes in atmospheric pressure.

The best watches are always timed in positions. There is of course much more friction when the pivots are rolling upon their sides than when turning upon their ends; gaining in the short vibrations tends to correct variation due to this. In general, timing in positions is a work of the very greatest difficulty, and perfect accuracy can only be obtained when the balance-spring weight of the balance and mainspring are in exact adjustment.

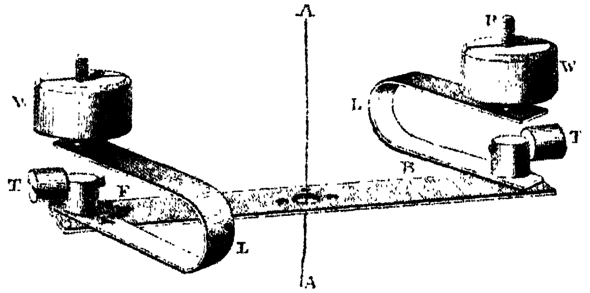

FIG. 21.

A very curious property sometimes exhibited by chronomoters is to gain upon their rates, that is to say, if the average daily rate of the chronometer were during the first month 1 second a day fast, during the second it would be 1½ seconds, and during the third month 2 seconds.

This arises from the balance-spring having been left at too high a temper after hardening. On the other hand, if the temper were left too low the chronometer would lose upon its rate. Glass springs exhibit the tendency to gain upon their rates to a remarkable degree.

Watch Escapements.

It would never do to have watch balances vibrating so small an arc as clock pendulums; the least we can do with is 200°, that is, 100 times as much. If you will remember the various clock escapements described, you will see that not one of them is suitable to fulfil such conditions, and something quite different had to be devised.

The form most generally employed is Mudge's detached lever, which is more in favour to-day than it ever was. P P are the pallets (see Fig. 22) mounted along with a lever, L L, upon a spindle, S. During the greater part of the swing of the balance, the lever and pallets are lying against either of the banking pins, B B. There is a notch, N, in the lever and a pin, I, to correspond upon the disc, R, which moves around along with the balance in the direction shown by the arrow. By-and-by the pin upon the disc will catch the notch in the lever and unlock the escape-wheel, a tooth of which is now being held against the dead face, D, of the pallet; the tooth will immediately slide along the slant, and deliver its impulse, which will be transmitted to the balance through the connection of the pin and disc R. The lever whilst resting against either of the banking pins is held in position by a little "draw" upon the dead faces of the pallets, that is, they are slanted back so that the pressure of the wheel teeth thrusts them away from it. There is also a safety disc, O, underneath the unlocking one, and a safety tongue in the lever, which, in the event of the watch getting a shake prevents its falling over to the opposite side of the balance-spindle to that where the unlocking pin is then situated.

People are continually "improving" this escapement, generally by making some slight alteration in the pins, but the broad principle and details always remain the same, as I have described them to you.

Another form of escapement very much used in foreign watches is the horizontal, invented by the same Graham already referred to; but as it does not possess qualifications for accurate time measurement, I shall not describe it.

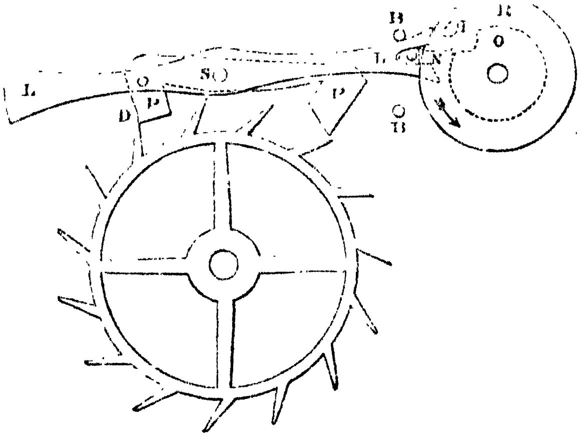

FIG. 22.

Our last escapement is that universally employed in chronometers (see Fig. 23); its original conception is apparently due to Arnold, though it was modified and greatly improved by Earnshaw. S S is the escape-wheel, which is now being held by the detent, D. R_1 R_2 are two discs, the smaller being situated in the plane of the detent, and the larger in the plane of the escape-wheel; both of them move upon the same spindle with the balance. The balance is now turning in the direction of the arrow; by-and-by the finger, P_2, upon the smaller roller will come round and lift away the detent, and the wheel will be free. The tooth, T, will then drop upon the impulse pallet, P_1, and deliver impulse to the balance. Meanwhile, the finger, P_2, gets clear of the detent, which it allows to fall just in time to receive the succeeding tooth of the escape-wheel.

The balance now passes on to the limit of its excursion, and returns; but in returning the finger does not interfere with the detent for the detent, D, is actually too short to reach it. Just now the finger really unlocked the detent by means of the little spring, Y Y, which is fastened some distance down the detent, the little spring being supported by the horn or extremity of the detent; but when the finger returns, it merely lifts out the spring, as there is upon this side no horn or extremity to support it.

Distribution of Time by Electricity—Chronographs.

To those acquainted with the difficulties in the way of communicating a uniform impulse to the pendulum through the medium of a train of wheel-work, it has always been a favourite idea directly to maintain the swing of the pendulum by means of an electric current, but, unfortunately, the thing has not hitherto proved feasible; apparently it must be taken for granted that the action of an electric current cannot be *constantly* maintained.

But although electricity is of little service for keeping clocks going, it has been very successfully employed in controlling them. It is, of course, very much more economical to have inferior clocks than good ones, and what is done in this case is to use one good clock for the purpose of controlling a quantity of bad ones. The nature of the apparatus is in general this: our first good clock and all the others are placed in the circuit of a galvanic battery, and what our first good clock does is to close the circuit and transmit a current at every beat of its pendulum. The passage of an electric current around a coil of copper wire (as you no doubt know) converts it for so long as it passes into a magnet, and this current so transmitted by the clock is employed for such a purpose, and the magnets so formed are constructed to operate upon the pendulums of the controlled clocks and accelerate them if they are lagging, or resist them if they should be moving too quickly.

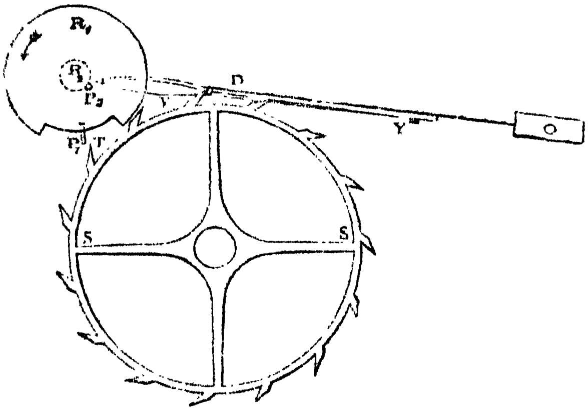

Fig 237

Electricity is also employed for the purpose of correcting the time of a clock, say once a day. In this case the clock which is to be corrected is kept at a slight gaining rate. Upon the axis of its escape-wheel is a little finger which revolves with it. At a few seconds before, say 1 o'clock, the controlling clock, by the transmission of a current, brings down an arm in front of the finger and stops the controlled clock for just so many seconds as it is in advance of the controlling clock; at 1 o'clock the arm is raised again, and the controlled and controlling clock start off approximately together.

Such a controlling clock as is used to transmit a current, say once a day, is also employed for the purpose of dropping time-balls and discharging guns. The time-ball itself is generally composed of wicker-work covered with canvas, and is wound up by hand to its position a few minutes before the transmission of the current, and held by a hook or detent. Upon the arrival of the current the detent (by what arrangement it is unnecessary to describe) is withdrawn, and the time-ball falls.

To discharge a time-gun, the current usually passes through a very fine platinum wire, which it makes red-hot. Both with time-balls and guns, and wherever it has heavy work to perform, the current from the clock is employed to close another and much more powerful circuit, the latter being that which operates upon the mechanism.

Instruments employed for the purpose of registering the passage of short intervals of time are called chronographs. These in the main consist of a cylinder covered around with paper revolving at a uniform rate. The rotation of those employed in observatories is generally controlled by what is called a conical pendulum, that is, a pendulum swinging round in the surface of a cone. Such pendulums are much more sensitive to any slight change in the pressure of the clock-train than ordinary oscillating pendulums, and require to be controlled by special apparatus. The pendulum used at Greenwich is so contrived, that when it endeavours to move faster (in doing so, of course swinging out further) it dips little spades into an annular trough of glycerine, and its velocity by this means is checked.

The operation of the apparatus is the following:—A pin upon the pendulum of the normal sidereal clock presses two weak springs together at every vibration, and so transmits a current. This current, by making an electro-magnet, brings down a striker upon the paper of the revolving cylinder. By an arrangement similar to a screw-cutting lathe, the frame carrying this striker just as the cylinder rotates, travels alongside of it, and the clock-beats are consequently indicated upon the cylinder in the form of a spiral of successive pricks. The mechanism attached to the clock is arranged so as to pass no current at the termination of each minute (the sixtieth second), and consequently a blank is left upon the cylinder, by which anybody can tell when the minute happened. Upon the same frame alongside the first striker is a second, which can be brought down by the observer at any one of the instruments, by touching a button at his side. His observation is consequently registered upon the barrel alongside the clock-beat, and you have no difficulty in determining its precise time of occurrence to the tenth or one-hundredth of a second.

Similar instruments are employed for determining the velocity of projectiles, but in these the cylinder travels at a much higher velocity, and other means of controlling it are made use of.

THE ARCTIC EXPEDITION

IT will of course be some time ere all the results obtained by the Expedition which has just returned from its year's sojourn on the edge of the ice-blocked Polar Sea can be presented to the public. Enough, however, is known to lead us to believe that abundant additions of the highest importance to our knowledge of the physics and natural history of the Arctic Regions have been made; and meantime we are able to exhibit in a map the main additions which have been made to Arctic geography.

The *Alert* and *Discovery*, under Captains Nares and Stephenson, left England in May, 1875. Godhavn was left on July 15, and all seems to have gone well till July 30, when, after leaving Port Foulke, the ice was met off Cape Sabine, 78° 41′ N., from which point the ships had a constant struggle with the pack to the north end of Robeson Channel. So close was the ice that occasion the water channel by which the ships advanced very soon closed behind them, rendering it as difficult to return as to proceed north. On August 25, after many hairbreadth escapes, a well-sheltered harbour was reached on the west side of Hall's Basin, north of Lady Franklin Sound, in lat. 81° 44′ N. Here the *Discovery* was secured for the winter, a few miles north of Polaris Bay, which was in sight on the opposite side of the channel.

The *Alert*, pushing onward, rounded the north-east point of "Grant Land," but instead of finding a continuous coast-line leading 100 miles further towards the north, as everyone had expected, found herself on the border of what was evidently a very extensive sea, with

impenetrable ice on every side. No harbour being obtainable, the ship was secured as far north as possible, inside a sheltering barrier of grounded ice, close to the land, and there she passed the winter; during her stay of eleven months no navigable channel of water permitting further advance to the northward ever presented itself. We believe that had an accident not happened to the screw of the *Alert* she would have endeavoured to push still further north; but the current round the corner of the land was so great she could not make headway. It was fortunate that the accident happened, for had she gone much further she would probably have got so jammed in the frightful ice-masses that it would have been impossible to get her out again. In lieu of finding an "open Polar sea," the ice was of most unusual age and thickness, resembling in a marked degree, both in appearance and formation, low floating icebergs rather than ordinary salt-water ice. It has now been termed the "Sea of Ancient Ice"—the Palæocrystic Sea; and a stranded mass of ice broken away from an ice-floe has been named a floe-berg. Whereas ordinary ice is usually from 2 feet to 10 feet in thickness, that in the Polar Sea, in consequence of having so few outlets by which to escape to the southward in any appreciable quantity, gradually increases in age and thickness until it measures from 80 feet to 120 feet, floating with its surface at the lowest part 15 feet above the water-line. In some places the ice is spoken of as reaching a thickness of from 150 to 200 feet, and the general impression among the officers of the expedition seems to have been that the ice of this "Palæocrystic Sea" is the accumulation of many years, if not of centuries, that the sea is never free of it and never open, and that progress to the Pole through it or over it is impossible with our present resources. It is interesting to note that the Aurora Borealis was not distinct in these latitudes, the latitude being supposed to be too high; this is consistent with the observations of the *Polaris* expedition, Dr. Bessels rarely finding the colours brilliant enough to give a spectrum.

When it was seen that further advance with the ships was impossible, all the energies of officers and men were directed to sledge-work. Sledge-parties were sent out northward, eastward, and westward, depôts having been established at intervals in the two former directions last autumn ready for the parties to be sent out during the spring of this year.

Although the two ships were only seventy miles from each other, it was impossible for any communication to pass between them till last March, when a party from the *Alert* succeeded in reaching the *Discovery* and relieving those on board the latter of any doubt as to the fate of their fellows. Owing to the high latitude of both ships the winter was unusually long and dark, the sun having been absent 142 days, and the cold was more intense than had ever been experienced by any previous expedition. All the old and a few new expedients were resorted to to relieve the unimaginable monotony of such a position, and apparently with great success. The lowest temperature observed was 104° below freezing, Fahr., at least 20° below the minimum observed by the *Polaris* expedition, and the mean temperature for thirteen consecutive days was 91° of frost; the mercury was frozen forty-seven days during the winter.

As soon as the sun appeared in the spring of this year active preparations were made for sledge-exploration, and by the beginning of April each ship was left with only half-a-dozen officers and men whose duties kept them on board. After that date sledges were continually arriving and departing, carrying forward provisions to be placed in depôt, ready for the return of the advanced parties.

Capt. Stephenson, besides looking after his own division, visited the *Alert*, and also made two trips across Hall's Basin to Greenland, and Capt. Nares started off like the rest, with Capt. Feilden, naturalist to the Expedition, immediately all the provision depôts were complete along the line of route, and the safety of the travellers insured. When at Polaris Bay Capt. Stephenson hoisted the American ensign and fired a salute as a brass tablet, which he and Capt. Nares had prepared in England, was fixed on Hall's grave. The plate bore the following inscription:—"Sacred to the memory of Captain C. F. Hall, of the U.S. ship *Polaris*, who sacrificed his life in the advancement of science on November 8, 1871. This tablet has been erected by the British Polar Expedition of 1875, who, following in his footsteps, have profited by his experience."

A party, headed by Commander Markham and Lieut. Parr, made a most gallant and determined attempt to push northwards by means of sledges. They were absent 72 days from the ship; and on May 12 succeeded in planting the British flag in lat. 83° 20′ 26″ N., within about 400 miles of the Pole. From this position there was no appearance of land to the northward, but, curiously enough, the depth of water was found to be only 70 fathoms. Owing to the extraordinary nature of the pressed-up ice, a roadway had to be formed by pickaxes for nearly half the distance travelled before any advance could be safely made, even with light loads; this rendered it always necessary to drag the sledge loads forward by instalments, and therefore to journey over the same road several times. The advance was consequently very slow, and only averaged about 1¼ mile daily—in fact, much the same rate attained by Sir Edward Parry in his somewhat similar attempt during the summer of 1827. Although the distance made good was only seventy-three miles from the ship, 276 miles were travelled over to accomplish it. It is quite impossible for any body of men ever to excel the praiseworthy perseverance displayed by this gallant party in their arduous struggle over the roughest and most monotonous road imaginable. Their journey, considering the ever-recurring difficulties, has eclipsed all former ones.

The result of their severe labour is held to prove the impracticability of travelling over the Polar Sea to any great distance from land, and also that Baron von Wrangell was perfectly correct in his expressed opinion that before the North Pole can be reached it is first necessary to discover a continuous coast line leading towards it.

In addition to the despatch of the northern travellers, the coast line to the westward of the *Alert's* position was traced for a distance of 220 miles by a party under the command of Lieut. Aldrich; the extreme position reached was in lat. 82° 10′ N., long. 86° 30′ W., the coast line being continuous from the *Alert's* winter quarters. The most northern land, Cape Columbia, is in lat. 83° 7′ N., long. 70° 30′ W. The coast of Greenland was explored by travelling parties from the *Discovery*, under the command of Lieutenants Beaumont and Rawson; they succeeded in reaching a position in lat. 82° 18′ N., long. 50° 40′ W., seventy miles north-east of Repulse Harbour. The land extended as far as lat. 82° 54′ N., long. 48° 33′ W., but very misty weather prevented its character being determined with exactness. The coast is much cut up into fjords and land was seen to the north-east, probably reaching to 83°. Lieut. Archer, with a party from the *Discovery*, explored Lady Franklin Sound, proving that it terminates at a distance of sixty-five miles from the mouth, with lofty mountains and glacier-filled valleys to the westward. Lieut. Fulford and Dr. Coppinger explored Petermann Fjord, finding it blocked up with a low glacier, which extends across from shore to shore. With the exception of Hayes Sound the coast line of Smith Sound has now been explored from north to south. President Land, marked in recent maps in about 84° N., is proved to have no existence, though Lieut. Aldrich, when engaged in pioneering the way for the main party, which was led by Commander Markham, advanced three miles beyond Sir Edward Parry's most northern position, and, from a mountain 2,000 feet high, sighted land towards the west-north-west, extending to lat. 83° 7'.

Ancient Eskimo remains were traced on the west side of Smith Sound up to lat. 81° 52' N. From that position the wanderers had evidently crossed the channel at its narrowest part to Greenland. The most diligent search was made further north, but no trace of them discovered.

Six musk oxen were shot at the *Alert's* winter quarters, and three half way between her position and that of the *Discovery*, while fifty-four were shot near Discovery Bay. The ermine was seen, and owls were found on the Greenland shore opposite the *Discovery's* quarters, the young ones on their appearance being mostly devoured by wolves. The remaining items in the *Alert's* game list at her northern station show seven hares and ninety birds of different kinds, the latter shot only in July. The birds certainly do not migrate beyond Cape Joseph Henry, lat. 82° 50' N. Very few besides those accounted for by the sportsmen passed the *Alert*. Very few seals were seen north of Cape Union, and no bears, dovekies, or looms, it is stated, ever reach the Polar Sea. Water animals were notably absent, and it is surmised that those that do visit the Arctic Sea come from the south. Among other birds visiting the country, but not advancing beyond the point mentioned, are the knots. Although no nests or eggs were found, the young in all stages of growth were obtained. Amongst the flora described by the parties from the *Alert*, were the saxifrage, sorrel, and dwarf oak, and late in the summer a few poppies were met with.

In the neighbourhood of the *Discovery's* winter quarters a seam of coal of good quality and readily worked, was discovered by Mr. Hart, naturalist; but, unfortunately, not before the present summer, otherwise it might have been of service during the winter, when the allowance of that article on board was necessarily kept as low as possible. Capt. Feilden obtained some fine fossil corals at the extreme northern hills. Very large collections of natural history subjects have been made by the naturalists, assisted by one and all of the officers and crew. The dredge and trawl were used on several occasions with great success. The observations on the physics and meteorology of the Arctic Regions are likely to prove of the greatest value when published. It will be remembered that during the stay of the *Polaris* in the north, the prevailing wind was from the north-east; during the present expedition scarcely any easterly wind was noticed at all, the prevailing wind, like the prevailing current, coming from the west.

All the *Polaris's* cairns were visited. At the boat depôt in Newman's Bay a box chronometer by Negus, New York, was found to be in perfect order after an exposure of four winters; it has since been keeping excellent time on board of the *Discovery*. Some wheat sent out in the *Polaris* in order to ascertain whether it would deteriorate when exposed to extreme cold, has been grown successfully under a glass shade by Dr. Belgrave Ninnis.

A magnificent series of photographs has been brought home, a selection of which will no doubt be published, and afford some idea of the strange scenery to be seen in these inhospitable regions.

Such is a brief summary of the results obtained by this latest Arctic expedition, but at what expense of hard work and suffering it is difficult for those who read the narrative to realise. The labour which had to be undergone would have been trying enough to perfectly healthy men, but unfortunately the dreaded scourge of Arctic explorers, scurvy, broke out among them. No expedition could have been better provisioned, but in spite of every precaution all the sledge parties suffered most severely. Notwithstanding this, every one worked determinedly and cheerfully. Only three seamen, however, died of scurvy, and only one death was the result of frostbite, that of Niels Christian Petersen, the interpreter of the expedition.

The ice in the Polar Sea remained firm until July 20, when there was a movement, increasing with each tide. On the 31st the *Alert* succeeded in leaving her winter quarters, and, after many struggles with the ice, joined company with the *Discovery* on August 12. Lady Franklin Bay remained closed until the 20th, when, a chance occurring, both ships were pushed into the ice, and succeeded in crossing. After this date the same kind of battle and slow progress took place daily between the ships and the ice, as during the passage north every inch gained being of importance as the ice closed in the rear. As the season advanced, or rather slipped away, many were the fluctuations in the social barometers as hopes and fears rose and fell, for it was not until September 9, the very last of the season, that the mouth of Hayes Sound was crossed, and the expedition again rejoiced in "open water."

The *Alert* reached Valentia on the 27th ult., and both ships arrived at Queenstown on the 29th. On Monday they left for Portsmouth, where they arrived on Wednesday morning. "It goes without saying" that everywhere officers and men have had the heartiest welcome, though no heartier than they deserve.

OUR ASTRONOMICAL COLUMN

μ DORADÛS.—This star, which was called a fifth magnitude by Lacaille at the end of 1751, and a sixth by Brisbane, was observed by Moesta from February, 1860, to January, 1861, of 8·9m. or 9m. only. Perhaps one of our southern readers will put upon record the actual magnitude of this star, the period of which, as Moesta remarked, would appear to be one of considerable length. Position for 1877·0 in R.A. 5h. 5m. 52s., N.P.D., 151° 58'.

SOUTHERN DOUBLE-STARS.—(1) α Centauri.—Measures of the angle of position and distance of this star, taken in the course of the ensuing year or two, will materially contribute towards defining within narrow limits the elements of the orbit. Even in Powell's last orbit, which was founded upon measures to January, 1870, the peri-astron passage (1874·2) is certainly too early, though each successive calculation of elements from Jacob's first has assigned a later date; it probably occurred in

(2) f Eridani also deserves close attention from the astrometer in the other hemisphere. There must be a great change in angle since the epoch of the last-published measures. The position (1877·0) is in R.A. 1h. 35m. 7s., N.P.D. 146° 49'.

THE INTRA-MERCURIAL PLANET QUESTION.—If in the general formula obtained by M. Leverrier, and given in last week's NATURE, we put $k = -1$, the solution, which gives for the sidereal period as referred to the node 27·964 days semi-axis major 0·180, and synodical period 30·282 days, accords with Stark's observation on October 9, 1819, one of the most definite upon record, besides representing, as well as the solution with $k = 0$, the five data upon which M. Leverrier has relied in deducing the formula. In this case we have—

$$\nu = 285^\circ{\cdot}76 + 12^\circ{\cdot}873724t - 10^\circ{\cdot}8 \cos \nu.$$

Stark's observation was published in his "Meteorologisches Jahrbuch," 1820. Under date, October 9, 1819, he says:—"At the same time there appeared, at a distance of 12' 28" from the southern limb of the sun, and 4' 58" from the eastern limb, a black, well-defined nuclear spot, which was perfectly round and of the size of Mercury. At 4h. 37m. this nuclear spot was no longer present, and I found also later on the 9th, as well as on the 12th, when the sun next came out, no trace of this spot." The observation was probably made about
Augsburg, which was one of Stark's usual hours for
the sun's disk—corresponding to October 8, at 23h. 1
wich time. For this time the above formula gives $\nu =$

and the earth's heliocentric longitude being 15°·3, the inferior conjunction of the assumed intra-Mercurial body with the sun would have occurred on the morning of Stark's observation.

THE FOURTH COMET OF 1857.—The best determined period of revolution of a comet, exceeding in length the period of the comet which appears to be associated with the August stream of meteors, is that of the fourth comet of 1857, discovered by Prof. C. H. F. Peters at Albany, U.S., on July 18, by Dien, at Paris, on the 27th, and by Habicht at Gotha, and Donati at Florence on the 30th of the same month. It was observed with the great refractor at the observatory of Harvard College till October 21. These dates include an interval of from about one month before to two months after the perihelion passage, or an arc on the orbit of 145°. A very complete discussion of the observations was made by Dr. Axel Möller, whose masterly investigations relating to the motion of Faye's comet have led to such accurate prediction of its apparent track in the heavens at recent returns; the period he assigns is 234·7 years. A similarly rigorous calculation led Dr. Hans Lind to a revolution of 243·05 years, and there are ellipses of nearly the same length of period by other computers.

If we examine the path of this comet through the planetary system we soon discover that it passes near to the orbit of Venus. Employing the elements of Axel Möller, a strict calculation shows that in heliocentric ecliptical longitude 24° 54′, the distance between the two orbits is less than 0·023 of the earth's mean distance from the sun. It may therefore be reasonably concluded that it is to an actual near approach of the comet to Venus about this point that the present form of orbit is due. The comet's perihelion distance is 0·747, the aphelion distance 75·35.

BIOLOGICAL NOTES

POCK-LYMPH.—The efficacy of pock-lymph has been attributed by several observers to the presence of small organisms of the nature of Micococcus. M. Hiller has recently studied this subject (*Centralblatt für d. Med. Wiss.*), and from 6,840 separate inoculations, he finds that the degree of activity of the lymph and the proportion of micrococci present do not correspond; on the one hand, the development of the organisms was often at its greatest when the action of the lymph was falling off, and on the other, lymph was often active, though no bacteria were perceptible in it. Fresh diluted lymph having been put in vertical tubes in a freezing mixture, and slowly thawed after freezing, the upper half gave on inoculation, 41·4 per cent. positive results, the lower half, 63·8 per cent. It appears from this that the poison is associated with the solid; constituents more than with the liquid. Boiled lymph was, without exception, inoperative. The addition of 1 to 4½ per cent. carbolic acid merely weakened the contagiousness of pock-lymph, while addition of glycerine left it unaltered. Strong dilutions weakened the action, while condensations exalted it; with evaporation, the percentage of favourable cases was increased about a half. In coagulated parts produced in the lymph, the active element was present in great quantity. Perfectly dried lymph is also active in high degree; hence we may infer that the communication of pox may occur by means of the crust and scurf of pustules which are rubbed off and float in the air. Inoculation with the blood of persons that were successfully inoculated proved inoperative; so also were the fresh contents of the bladders, seven days after inoculation. It is inferred that the cow-pox ferment is not contained in the blood, or not in the active state; and that very probably, also, the blood is not itself the seat of fermentation and reproduction of the poison.

ALGOID SWARM-SPORES.—If vessels of water containing algæ are placed in a room where they are lighted only on one side, swarm-spores are generally found to collect at the side turned towards the window, more rarely on the opposite side. If they are present in considerable number, they often become arranged in peculiar cloudy forms; network, rays, tree-like branched figures, &c. The phenomenon has been frequently studied, and has been always regarded as an action of light, causing the living swarm-spores to move towards it or withdraw from it. After a long investigation of the phenomena, M. Sachs has come to a different conclusion. He considers that these groupings of zoospores are not phenomena of life, inasmuch as quite a similar process is found to occur with emulsions of oil in alcohol diluted with water; also that the light either does not at all participate in the action, or does so only indirectly, for all the phenomena may be reproduced in darkness. The accumulation of spores and the cloud-like figures are rather due to currents produced by differences of temperature in the water. M. Sachs's experiments are described in *Flora*, 1876, No. 16.

DISEASES GERMINATED IN HOSPITALS.—Several observers have remarked on the presence of globules of pus and microscopic algæ in the air and on the walls of hospitals. Some interesting facts of this order have recently been communicated to the French Société de Biologie, by M. Nepveu of the laboratory of La Pitié. A square metre of the wall of a surgery-ward, having been washed, after two years without washing, the liquid pressed from the sponge (about 30 gr.) was examined immediately after. It was somewhat dark throughout and contained micrococcus in very great quantity (fifty to sixty in the field of the microscope), some micro-bacteria, a small number of epithelial cells, a few globules of pus, some red globules, and lastly a few irregular dark masses and ovoid bodies of unknown nature. The experiment was made with all necessary precautions; the sponge employed was new, and carefully washed in water that was newly distilled. Facts like those referred to make it easy to comprehend how the germs of a large number of diseases occur in the air of hospitals, and how the latter may readily become centres of infection. *The same conditions, though in less degree, may sometimes be met with in private life.*

MARINE MOSSES.—M. Gisard lately showed to an audience at the Congress of learned societies at the Sorbonne, specimens of marine mosses growing on a madrepore placed in an aquarium, since January, 1872. They produce every year, in spring, phenomena of fructification, consisting of urns of a superb nacreous colour, growing at the ends of beautiful green filaments, then becoming detached and rising to the surface of the water. He cited the following fact as showing the vitality of certain marine plants. On May 13, 1875, a parcel of algæ which had been taken from an aquarium and dried several months in the sun, was placed in sea-water, and developed a magnificent green plant of ribbon form. In February and March, 1876, there were formed on the border of the ribbon sparse filaments carrying rounded urns of variegated colour, which became detached, and rose to the surface, giving rise to green plants.

NOTES FROM ST. PETERSBURG.—At the last meeting, October 18, of the Zoological Section of the St. Petersburg Society of Naturalists, Prof. Wagner gave some information as to his recent researches made in the Solovetsky Bay of the White Sea. The special aim of them was to throw some light on the causes which determine the use in certain organisms, as for instance the hydroids, of two different modes of reproduction, sometimes by gemmation, and sometimes with the help of special organs. Without coming to any decided conclusions (the researches having to be continued) M. Wagner pointed out, as one possible cause of this difference, the influence of different nutrition which generally so greatly influences the reproductive functions. M.

Cherniaffsky, who has been many years engaged in the study of the fauna of the Black Sea, and now studies especially the influence of the media on organic forms, reported upon his numerous collections of animals from various depths, and traced in them the slow variations which animals of the same species undergo at different depths, and the appearance of new species with the increase of depth; the labours of M. Cherniaffsky promise to be of great interest when published in full.

COLOURS OF ANIMALS.—At the last meeting of the St. Petersburg Entomologists' Society, October 16, M. Porchinsky reported upon some results on the exploration of a scientific party engaged last summer upon the exploration of the Caucasus. The southern limit of the region explored was the Steppe of Erivan, a plain covered with sand, with some patches of variously coloured clays appearing in the low hills. A remarkable feature of the animal inhabitants of the Steppe, insects and reptiles, and especially of the lizards, is the most perfect coincidence of their colouring with the colouring of the Steppe. The same thing was observed also in the Steppe of Elizabethpol. Interesting collections of the fauna made by the party were produced at the meeting.

NOTES

DR. CARL JELINEK, the eminent and accomplished meteorologist, died at Vienna on October 19, after a protracted illness.

THE death is announced, on the 16th ult., of Dr. von Waltershausen, Professor of Mineralogy and Geology at Göttingen, where he was born in 1809. While young he travelled much, especially in Sicily and Iceland, making large mineralogical collections, which he presented to the university. He is specially known for his researches in connection with volcanic phenomena. During his later years he was engaged in a large work on the topography and orography of Etna.

PROF. H. J. S. SMITH's valedictory address to the London Mathematical Society, on the 9th inst., will touch upon various points affecting the present state and prospects of pure mathematics.

THE popular German poet and mineralogist, Prof. von Kobell, has just celebrated, in Munich, the fiftieth anniversary of the day on which he was appointed extraordinary professor of mineralogy in that city.

DR. RÖNTGEN has been appointed extraordinary Professor of Physics in Strasburg University.

DR. CARPENTER, F.R.S., Secretary to the Gilchrist trust, has, for the special benefit of the Primary Teachers of the Metropolis, arranged for a course of lectures to be given by Dr. Richardson, F.R.S., at St. Thomas Charterhouse Schools, on Human Physiology, and its application to daily life. The course will be opened on Friday, November 3, by Dr. Carpenter, delivering an address on a Sound Mind in a Sound Body.

WILLIAM CLARKE MILLER, B.A. Lond., vice-principal of Huddersfield College, has been elected Registrar of the General Medical Council of Education in the place of Dr. Erasmus Hawkins, resigned. The new Registrar has been long known as an able mathematician.

IT is stated by the *Medical Press and Circular* that the Goldsmith's Company has voted a sum of 1,000*l.* to the Chemical Society to aid in the formation of the fund to be devoted to the promotion of original research in the science of chemistry.

M. WADDINGTON, the intelligent Minister of Public Instruction in France, has come to a most liberal decision on behalf of the Paris Observatory. According to the standing financial rules used in France, no adjudicator of works executed in the public interest is entitled to be paid except when his task has been completed and received. As an exception, M. Leverrier is authorised to pay in advance to the opticians and philosophical instrument makers a sum amounting to one-third of the total value

instrument, which has been so delayed by the red-tapeism of the Finance Department, is almost finished, and observations will very shortly be inaugurated in the new pavillion which has been built on an improved scheme for its reception.

M. FEIL, the glass-worker of Paris, has just finished the casting of the crown-glass lens for the great Vienna refractor. The diameter is 28 inches and the weight 112 pounds. It will be sent immediately to Mr. Howard Grubb, of Dublin, who already possesses the flint lens.

THE course of lectures at the Sorbonne for candidates for the *licence* and pupils of the Normal Schools was opened a few days since. In former years the lecturers were confined to merely elementary subjects relating to mechanics, classics, astronomy, differential and integral calculus. But this year M. Bonnet lectures on the recent discoveries in high geometry, and M. Puiseux on a subject which has been largely discussed by men of science in England, the figure that the earth must have taken owing to its fluidity.

WITH exception of the schools of Paris, which rank among the first in the world, most of the faculties of sciences and *lettres* in France (says M. Grad in *La Nature*) have only five professors. Now there were a hundred and thirty-five at the University of Berlin, seventy at the University of Königsberg, against three hundred and forty-eight in all the faculties of the fifteen academical divisions of France in 1870. The faculty of sciences and that of *lettres* of Strasburg, more favoured than others, had then thirteen professors, against thirty-six in the faculty of philosophy and sciences of the present University. The University at present has a total of eighty professors

buted among the five faculties of theology, law, medicine, philosophy, and natural and mathematical sciences. This year Prussia devotes to the maintenance of its nine universities 6,577,397 marks, of which 4,820,841 marks are furnished from the State Treasury. With regard to population, the expenditure per head of inhabitants is 0·70 fr. in Alsace-Lorraine, 0·12 fr. in France, 0·33 fr. in Prussia.

A COMMITTEE appointed by the Russian Government at the St. Petersburg Medical Academy to investigate various proposed antiseptics and disinfectants, have arrived at the following conclusions:—1. Carbolic acid is the most efficient means against the development of ammoniacal gas, putrescence, and development of lower organisms in organic matter under decomposition, and it is therefore the best antiseptic. 2. Vitriol, salts of zinc, and charcoal, are the best means for deodorising matter under putrefaction. 3. The powders of Prof. Kittary, besides the properties they share in common with other carbolic disinfectants, deserve attention because of the isolated state of phenol in them and their contents of quick-lime, which absorbs moisture—the principal condition of each kind of putrefaction—as also some part of the gases. 6. Chloride of lime and permanganate of potash quickly destroys the lower organisms in putrid liquids. 7. The disinfectants certainly retard the putrid processes in organic bodies, but their influence is only temporary, as a means of puri-

air in dwellings their influence is very small if not *nil*, because of the very small degree of concentration of their ingredients that can be used without injuring the health of inhabitants. 9. For uninhabited buildings the best disinfectants are nitrous acid and chlorine.

Referring to our recent correspondence on "Antedated Books," a correspondent calls attention to another evil practice that has of late years crept into the publishing trade, namely, that of publishing books without any date at all. Our correspondent mentions two firms that sin extensively in this respect; but there are several others, especially in what is known as the "number trade," who of *malice prepense* publish undated books. Such books are generally of small literary or scientific value, but circulate among a class who are generally unable to test their value. Of course the purpose of issuing undated books is evident; works half a century old may be palmed off on the unknowing as the genuine product of the current year.

We understand that Dr. A. Wojeikoff, of St. Petersburg, has arrived at Singapore from Batavia on his way to Japan, on what may be truly characterised as a meteorological tour, at his own expense, over the whole civilised world. The tour was begun upwards of seven years ago, when the greater part of Europe was visited, and after a return to and brief residence in Russia, was again resumed through the United States, extending as far as Manitoba, and thence southwards through South America, and onwards to the East India Islands. Those who have had the pleasure of meeting him know that this tour means a large amount of meteorological work, in the prosecution of which he has made prolonged sojourns in different regions with the view of familiarising himself practically with their meteorology and with the steps which have been taken towards its investigation. The training which this able meteorologist is giving himself well deserves our warmest commendation.

As being somewhat analogous to the above, it may be notified that Dr. Hamberg, meteorological assistant to Prof. H. Hildebrandsson, of Upsal University, is at present engaged on a year's tour through Europe for the purpose of familiarising himself with the systems of meteorological research pursued in different countries, funds for the purpose having been provided by the Upsal University. This is real professional education, and deserves to be carried out more extensively and in a more Catholic spirit than has yet been done by our British Universities.

We have received from Prof. Dove the *Monatliche Mittel für Druck, Temperatur, Feuchtigkeit, und Niederschläge und fünftägige Wärmemittel* for 1875. In addition to the usual meteorological results, this admirable annual serial gives the five-day means of temperature for the year and their departure from the means of the twenty years ending 1867, and the same for ten Austrian, thirteen Swiss, and twenty-four Italian stations, thus presenting in a clear manner the temperature conditions of Germany, and their relations to those of immediately surrounding regions during 1875. The results of the observations made at the Forest-stations of Bavaria and additional rain returns are also given, together with a most valuable *résumé* of the monthly amounts of rainfall observed at all stations in Germany during the past five years, and monthly and annual averages of rainfall calculated from all the past observations at each place as are available. The latitude, longitude, and height of the Austrian, Swiss, and Italian stations are stated, and we very earnestly hope that, with next issue, Prof. Dove will be able to give the data for his stations in Germany, the want of which is felt to be a serious omission in nearly all discussions of German meteorology.

In a paper in this month's Petermann's *Mittheilungen* Prof. H. Fritz treats of the Geographical Distribution of Hail. He refers to our comparative ignorance of the origin and peculiarities of the appearance of hail, of the want of long series of observations on the subject, and in those that do exist of the frequent confounding of hail and graupel—the balls of true hail having an icy structure, whereas the balls of graupel are only small pellets of snow. The latter he shows falls in all latitudes and at all heights; while hail is mainly confined to middle latitudes. In high latitudes and in tropical valleys, hail is a rare phenomenon. Prof. Fritz brings together for comparison observations on the subject made in various quarters of the globe, the statistics being, as might be expected, fullest in the case of Europe. The following are some of his conclusions from these data:—He infers that hail occurs whenever the moisture of the atmosphere is precipitated in very great quantity as rain or snow, and that hail phenomena correspond to the amount of this excess of precipitation. With increase in latitude and in height the fall of graupel increases and that of hail decreases, while hailstones of large size are most frequent towards the equator. But since in the low lands of the tropics hail is little known, the regions of the most frequent and especially most destructive hailstorms belong to the middle latitudes, while in high and low latitudes hail-falls of large stones are exceptional. It appears then that no region in which an excessive rainfall occurs is secure against hailstorms, if only the height of fall is sufficient to allow of the formation of hail. In high latitudes and in high table-lands the vertical distances to the atmospheric strata with temperature below zero are small, and therefore more snow and graupel will fall than hail, while in middle and low latitudes this distance, especially in summer, is great enough to allow of the formation of large hailstones. North and south of the zone of calms the hail-fall becomes more frequent reaches its maximum between 40° and 60° of latitude. The currents of the atmosphere and the formation of the land-masses have also an influence on the distribution of hail. A satisfactory solution of the hail question can, however, only be obtained by complete series of observations, the details for each station being given separately, and the distinction between true hail and graupel being attended to.

The German Society for Arctic Exploration (Bremen) has just heard from Drs. Finsch and Brehm. They speak of the most difficult part of their journey from the Ob to the Kara Sea through a hitherto quite unknown region, which they performed partly in boat, partly by reindeer, and partly on foot, over the Tundras. The knowledge obtained by the expedition in this region is an important contribution to the geography of West Siberia. The collections with reference to the ethnology of the Samoyeds and Ostiaks are especially valuable, as also the specimens of birds and fishes. The travellers expected to be home by the beginning of this month.

Prof. James Orton, of Vassar College, U.S., has nearly completed his preparations for the exploration of the river Beni, a little known tributary of the Madeira River, the largest affluent of the Amazon. Prof. Orton sums up the special objects of the survey as follows: 1. To solve some of the most interesting and important geographical problems of the day. 2. To search for the traces of the ancient military roads, probably built by the Inca Yupanqui when he invaded that region. 3. To open up the trade of the eastern slope of the Andes with the United States. In Prof. Orton's opinion, the search for the source of the Nile, while of not greater interest than that of the Beni, is of very much less commercial value.

In a paper on "The Climate Controversy," published in the two last numbers of the *Geological Magazine*, Mr. Searles V. Wood, jun., discusses the possible cause of the latest changes of climate experienced by the earth. The aim of Mr. Wood is less to advocate some special solution of the question than to insist on the difficulties which beset all the theories hitherto offered as a solution, and which are (1) a decrease in the original heat of our planet; (2) changes in the obliquity of the ecliptic; (3) the combined effect of the precession of the equinoxes and of the excentricity of the earth's orbit; (4) changes in distribution of land and water; (5) changes in the position of the earth's axis; (6) a variation in the amount of heat radiated by the sun; and (7) various temperatures of those regions of space through which the solar system has moved. Discussing each of them, Mr. Wood deals at greater length with the theory advocated by Mr. Croll, arriving at the conclusion that, although the influence of geographical conditions and currents is a powerful agent in modifying climate, nevertheless the cause of the Glacial period must have been a cosmical one; that the cold of this period seems to have fallen upon the earth while its axis was in its present position; and that nothing has yet been found to raise a doubt as to the glaciation of the northern and southern hemispheres having been synchronous. Mr. Wood inclines to admit that it is to the sixth suggested cause, a diminution in the heat emitted by the sun, that the probabilities incline. The discussion of the geological facts connected with the latest changes of climate is the main attraction of the paper of Mr. Wood.

CAPT. ALLEN YOUNG's Arctic ship *Pandora* is back again, all well. It will be remembered Capt. Young went out to endeavour to communicate with the Arctic expedition, which he met on its road home.

Two shocks of earthquake were felt at Irkutsk and its neighbourhood, on August 31 at 10 P.M., and on September 4 at 1.30 A.M. Both extended over a large region, and the last was rather strong at Irkutsk.

Two earthquakes are reported as having occurred in Germany on October 14, the one near Kehl at 11 A.M., and the other at Schopfheim between 8.30 and 9 P.M. The former extended over Strasburg, Kehl, Kork, Auerheim, Zierolshofen, Leutesheim, Linz, Diersheim, Rhein-Bischofsheim; the direction was apparently in a south-west-north-east direction. There were three or four shocks lasting about four seconds. The other earthquake was to the north of Schopfheim, at Neuenweg and Gresgen, and was of shorter duration than the former; the direction was apparently north-south.

THE African explorer, Eduard Mohr, writes to Dr. Nachtigal, under date August 28, of his arrival at St. Paul de Loanda. Within eight days he was to proceed to Malange, on the eastern limit of Angola, which he was to make his base of operations for an exploring journey to the northern interior.

IN the Geological Section of the Helvetic Society of Sciences, besides many interesting smaller communications, the following larger contributions to geological science were made:—The results of a thorough exploration of the earlier geological history of the Black Forest and of the Vosges, by Prof. Sandberger; the results of explorations in the Argovian Jura, by Prof. Muhlberg; the results of explorations by M. Mœsch in the Bernese Alps, accompanied by a map of the mass of the Faulhorn and of its neighbourhood; a map on the scale of 1:250,000 of the glacial deposits of Switzerland, with full particulars as to the former extension of glaciers, their depths, slopes, &c., made by Prof. Favre; and a very detailed map, on a scale of 1:5,000, of the glacier of the Rhone, with all its moraines, moulins, crevices, &c., constructed by M. Gosset, at the charge of the Swiss Alpine Club.

AT the same meeting Prof. Sandberger presented his work "Land- und Süsswasser-Conchylien der Vorwelt." The terrestrial and fresh-water molluscs are described here in these geological succession, beginning from the oldest formations. Being very abundant in the Tertiary deposits, they have, as is known, much contributed to settle the classification of these deposits.

AT the *conversazione* of the Chester Society of Natural Science held last month, Mr. Cross exhibited some specimens of *Drosera rotundifolia* which had been grown in Mr. Siddall's fern case, and which presented characters differing greatly from those of the typical plant. The axis had elongated considerably and bore a number of alternate leaves, quite green, with aborted tentacles, and several of them showing buds produced on the mid-rib. Some of the old leaves of the original plants placed in the case for preservation also exhibited the phenomenon last named.

WE have received from Dr. C. A. MacMunn an account of the method he proposes for measuring and comparing different spectra with the spectrum microscope. In order to overcome the difficulties due to the difference in the dispersion of different prisms, he proposes to look upon the distance between the Fraunhofer lines B and E as equal to 100, and to express the position of all bands in relation to this scale. We, however, think that it is very desirable not to multiply the already too numerous arbitrary scales of this kind, and would strongly advise him and all others who are studying this subject, to express their results in terms of wave lengths, since, as Mr. Sorby has argued, that system alone has a true physical basis.

THE Bethnal Green Museum is becoming just now a great centre of attraction to the multitudes from the numerous interesting collections illustrative of art and science now deposited together. The former speak to the eye for themselves, although the Secretary of the Department has taken care to provide admirable historical and descriptive cheap catalogues. But the scientific and industrial collections require more carefully prepared aids for study, and these are now being furnished by the Department in illustrated manuals, published at a cheap price, written by eminent authors, and on these no expense has been spared to make them thoroughly practical and useful treatises upon the subjects on which they treat. Messrs. Chapman and Hall, we are informed will publish immediately for the Council of Education and Department of Science, three of these works—"Food, its Chemical Constituents and Uses," by Mr. A. W. Chunt, F.C.S., Professor at the Royal Agricultural College, Cirencester; "Economic Entomology," by Mr. Andrew Murray, F.L.S., and "Animal Products, their Preparation, Commerce, and Uses," by Mr. P. L. Simmonds.

THE additions to the Zoological Society's Gardens during the past week include a Cape Hyrax (*Hyrax capensis*) from South Africa, presented by Mr. J. M. Thornton; an Ocelot (*Felis pardalis*) from Honduras, presented by Mr. H. Fielding; two Norwegian Lemmings (*Lemmus norvegicus*) from Norway, presented by Mr. W. Duppa Crotch; a Common Hangnest (*Icterus vulgaris*) from South America, presented by Mr. J. T. Levett; an African Cobra (*Naia haje*) from South Africa, presented by the Rev. G. H. R. Fisk; a Vervet Monkey (*Cercopithecus lalandii*) from South Africa, deposited; two Indian Cobras (*Naia tripudians*) from India, received in exchange; a Merlin (*Hypotriorchis æsalon*), European, purchased.

SEXUAL SELECTION IN RELATION TO MONKEYS

IN the discussion on Sexual Selection in my "Descent o Man," no case interested and perplexed me so much as the brightly-coloured hinder ends and adjoining parts of certain monkeys. As these parts are more brightly coloured in one sex than the other, and as they become more brilliant during the season o love, I concluded that the colours had been gained as a sexua attraction. I was well aware that I thus laid myself open to ridicule; though in fact it is not more surprising that a monkey should display his bright-red hinder end than that a peacock should display his magnificent tail. I had, however, at that time no evidence of monkeys exhibiting this part of their bodies during their courtship; and such display in the case of bird affords the best evidence that the ornaments of the males are o service to them by attracting or exciting the females. I have latel read an article by Joh. von Fischer, of Gotha, published in *Der Zoologische Garten*, April, 1876, on the expression of monkeys under various emotions, which is well worthy of study by any one interested in the subject, and which shows that the author is a careful and acute observer. In this article there is an account of the behaviour of a young male mandrill when he first beheld himself in a looking-glass, and it is added, that after a time he turned round and presented his red hinder end to the glass. Accordingly I wrote to Herr J. von Fischer to ask what he supposed was the meaning of this strange action, and he has sent me two long letters full of new and curious details, which will, I hope, be hereafter published. He says that he was himself at first perplexed by the above action, and was thus led carefully to observe several individuals of various other species of monkeys, which he has long kept in his house. He finds that not only the mandrill (*Cynocephalus mormon*) but the drill (*C. leucophæus*) and three other kinds of baboons (*C. hamadryas*, *sphinx*, and *babouin*), also *Cynopithecus niger*, and *Macacus rhesus* and *nemestrinus*, turn this part of their bodies, which in all these species is more or less brightly coloured, to him when they are pleased, and to other persons as a sort of greeting. He took pains to cure a *Macacus rhesus*, which he had kept for five years, of this indecorous habit, and at last succeeded. These monkeys are particularly apt to act in this manner, grinning at the same time, when first introduced to a new monkey, but often also to their old monkey friends; and after this mutual display they begin to play together. The young mandrill ceased spontaneously after a time to act in this manner towards his master, von Fischer, but continued to do so towards persons who were strangers and to new monkeys. A young *Cynopithecus niger* never acted, excepting on one occasion, in this way towards his master, but frequently towards strangers, and continues to do so up to the present time. From these facts von Fischer concludes that the monkeys which behaved in this manner before a looking-glass (viz., the mandrill, drill, *Cynopithecus niger*, *Macacus rhesus*, and *nemistrinus*) acted as if their reflection were a new acquaintance. The mandrill and drill, which have their hinder ends especially ornamented, display it even whilst quite young, more frequently and more ostentatiously than do the other kinds. Next in order comes *Cynocephalus hamadryas*, whilst the other species act in this manner seldomer. The individuals, however, of the same species, vary in this respect, and some which were very shy never displayed their hinder ends. It deserves especial attention that von Fischer has never seen any species purposely exhibit the hinder part of its body, if not at all coloured. This remark applies to many individuals of *Macacus cynomolgus* and *Cercocebus radiatus* (which is closely allied to *M. rhesus*), to three species of Cercopithecus and several American monkeys. The habit of turning the hinder ends as a greeting to an old friend or new acquaintance, which seems to us so odd, is not really more so than the habits of many savages, for instance that of rubbing their bellies with their hands, or rubbing noses together. The habit with the mandrill and drill seems to be instinctive or inherited, as it was followed by very young animals; but it is modified or guided, like so many other instincts, by observation, for von Fischer says that they take pains to make their display fully, and if made before two observers, they turn to him who seems to pay the most attention.

With respect to the origin of the habit, von Fischer remarks that his monkeys like to have their naked hinder ends patted or stroked, and that they then grunt with pleasure. They often also turn this part of their bodies to other monkeys to have bits of dirt picked off, and so no doubt it would be with respect to thorns. But the habit with adult animals is connected to a certain extent with sexual feelings, for von Fischer watched through a glass door a female *Cynopithecus niger*, and she during several days, "umdrehte und dem Männchen mit gurgelnden Tönen die stark geröthete Sitzfläche zeigte, was ich früher nie an diesem Thier bemerkt hatte. Beim Anblick dieses Gegenstandes erregte sich das Männchen sichtlich, denn es polterte heftig an den Stäben, ebenfalls gurgelnde Laute ausstossend." As all the monkeys which have the hinder parts of their bodies more or less bright coloured live, according to von Fischer, in open rocky places, he thinks that these colours serve to render one sex conspicuous at a distance to the other; but as monkeys are such gregarious animals, I should have thought that there was no need for the sexes to recognise each other at a distance. It seems to me more probable that the bright colours, whether on the face or hinder end, or, as in the mandrill, on both, serve as a sexual ornament and attraction. Anyhow, as we now know that monkeys have the habit of turning their hinder ends towards other monkeys, it ceases to be at all surprising that it should have been this part of their bodies which has been more or less decorated. The fact that it is only the monkeys thus characterised which, as far as at present known, act in this manner as a greeting towards other monkeys, renders it doubtful whether the habit was first acquired from some independent cause, and that afterwards the parts in question were coloured as a sexual ornament; or whether the colouring and the habit of turning round were first acquired through variation and sexual selection, and that afterwards the habit was retained as a sign of pleasure or as a greeting, through the principle of inherited association. This principle apparently comes into play on many occasions: thus it is generally admitted that the songs of birds serve mainly as an attraction during the season of love, and that the *leks*, or great congregations of the black grouse, are connected with their courtship; but the habit of singing has been retained by some birds when they feel happy, for instance by the common robin, and the habit of congregating has been retained by the black grouse, during other seasons of the year.

I beg leave to refer to one other point in relation to sexual selection. It has been objected that this form of selection, as far as the ornaments of the males are concerned, implies that all the females within the same district must possess and exercise exactly the same taste. It should, however, be observed in the first place, that although the range of variation of a species may be very large, it is by no means indefinite. I have elsewhere given a good instance of this fact in the pigeon, of which there are at least a hundred varieties differing widely in their colours, and at least a score of varieties of the fowl differing in the same manner; but the range of colour in these two species is extremely distinct. Therefore the females of natural species cannot have an unlimited scope for their taste. In the second place, I presume that no supporter of the principle of sexual selection believes that the females select particular points of beauty in the males; they are merely excited or attracted in a greater degree by one male than by another, and this seems often to depend, especially with birds, on brilliant colouring. Even man, excepting perhaps an artist, does not analyse the slight differences in the features of the woman whom he may admire, on which her beauty depends. The male mandrill has not only the hinder end of his body, but his face gorgeously coloured and marked with oblique ridges, a yellow beard, and other ornaments. We may infer from what we see of the variation of animals under domestication, that the above several ornaments of the mandrill were gradually acquired by one individual varying a little in one way, and another individual in another way. The males which were the handsomest or the most attractive in any manner to the females would pair oftenest, and would leave rather more offspring than other males. The offspring of the former, although variously intercrossed, would either inherit the peculiarities of their fathers, or transmit an increased tendency to vary in the same manner. Consequently the whole body of males inhabiting the same country, would tend from the effects of constant intercrossing to become modified almost uniformly, but sometimes a little more in one character and sometimes in another, though at an extremely slow rate; all ultimately being thus rendered more attractive to the females. The process is like that which I have called unconscious selection by man, and of which I have given several instances. In one country the inhabitants value a fleet or light dog or horse, and in another country a heavier and more powerful one; in neither country is there any selection of the individual animals with lighter or stronger bodies and limbs; nevertheless after a considerable lapse of time the individuals are found to have been modified in the desired manner almost uniformly, though differently in each country. In two absolutely distinct countries inhabited by the same species, the individuals of which can never during long ages have intermigrated and intercrossed, and where, moreover, the variations will probably not have been identically the same, sexual selection might cause the males to differ. Nor does the belief appear to me altogether fanciful that two sets of females, surrounded by a very different environment, would be apt to acquire somewhat different tastes with respect to form, sound, or colour. However this may be, I have given in my "Descent of Man" instances of closely-allied birds inhabiting distinct countries, of which the young and the females cannot be distinguished, whilst the adult males differ considerably, and this may be attributed with much probability to the action of sexual selection.

CHARLES DARWIN

SCIENTIFIC SERIALS

THE *Bulletin de l'Academie Impériale des Sciences de St. Pétersbourg*, t. xxii., No. 1, contains the following papers of scientific interest:—On the absorption of carbonic acid by sulphuric acid and its mixtures with water, by J. Setschenow.—On tartronamic acid, by N. Menschutkin.—On ethyl- and methylsuccinimid, by the same.—On the geological age of the North-Caucasian Jura coal sandstones, and on natural saltpetre occurring in the same in the valley of Kuban, by H. Abich.—On diethyl-methyl-acetic acid, a new isomeric variety of œnanthylic acid, by M. E. Idanow.—On the formation of buds in *Equisetum*, by Prof. A. Famintzin.—Observations made at the astronomical observatory of the Academie des Sciences de St. Petersbourg, by A. Sawitch.

Journal de Physique, September.—M. André here investigates the subject of diffraction in optical instruments and its influence on astronomical observations. He shows that the diameter of Venus and Mercury during transit must always be less than in ordinary conditions of observation, and less by day than by night, with an instrument of the same aperture; also that it is less, the smaller the aperture of the instrument, the variation being equal to the difference of constants of instrumental diffraction of the instruments employed.—It is known that sulphur affects two incompatible crystalline forms, the right octahedron with rectangular base, and the symmetrical oblique prism. M. Gernez specifies the circumstances in which they are produced without intervention of any solvent.—M. Egoroff gives a description, with figure, of his differential electro-actinometer, an instrument for determining the co-efficients of absorption of ultra-violet rays by different substances.—M. Lecoq de Boisbaudran describes the physical properties of gallium. *Inter alia*, even a few degrees under its point of fusion + 29°·5, it is hard and remarkably tenacious for a metal so fusible; it can be cut, however, with a knife. It crystallises with great facility. The spectrum got by passing the spark in a saline solution, has two violet lines, the brighter with wave length 417·0, the other 403·1. In gas flame the former is hardly observable. The density is 4·7; the equivalent, not yet quite fixed, seems to be near the number deduced from the position of gallium between iodium and aluminium.

Sitzungsberichte der naturwissensch. Gesellsch. Isis in Dresden, July to December, 1875.—In this number will be found an interesting account of the Auckland Islands, by M. Hermann Krone, of the German Transit Expedition. The copper-bearing strata of Lake Superior, a potato exhibition at Altenburg, in October, Dr. Dohrn's zoological station at Naples, and an instance of lightning with a clear sky, are among other subjects treated; there are also a few archæological papers.

SOCIETIES AND ACADEMIES

PARIS

Academy of Sciences, October 23.—Vice-Admiral Paris in the chair.—The following papers were read:—Theorems relating to systems of three segments forming a constant length, by M. Chasles.—Remarks on a critique of Dr. Boué on the theory of *trombes*, by M. Faye. The gyration of the base of a trombe is generally too rapid to be perceived; but on reaching the ground or the sea, a quantity of dust or of water-droplets is raised by the escaping air, and passes obliquely before the trombe, with a perceptible slow movement. The spectator may by mistake attribute this motion to the trombe itself, and conclude that the trombe pumps the water (*e.g.*) up to the clouds. The trombe's motion is really a descending gyratory one.—On the order of appearance of the first vessels in the aerial organs of *Anagallis arvensis*, by M. Trécul.—Report to the Academy on the works of M. Francis Garnier, naval lieutenant. M. Garnier died about three years ago. His travels in China have had important results. The Minister of Public Instruction, on the recommendation of the Academy, has appointed an annual pension of 1,200 francs to be given to his widow.—Note on electric effluves, by M. Boillot. To obtain the dark effluves the conducting tubes for the electricity should be sufficiently apart to prevent any phosphorescent glow in the darkness. M. Boillot describes some modifications of his apparatus.—On determination of the depth of the sea by means of the bathometer, and without use of a sounding line, by Dr. C. W. Siemens.—On the industrial applications of phosphuret of copper and phosphorised bronze, by MM. de Ruolz, Montchal, and De Fontenay. Of two bells presented to the Academy, one made with phosphuret of copper in proportion of $\frac{8}{100}$ gave sounds much superior in acuteness, intensity, and timbre, to those of the other bell, which was of an ordinary bronze (78 copper, 22 tin). Its composition was also more homogeneous. By reducing the proportion of phosphorus to a few thousandths, red copper may be cast in sand without its physical properties being sensibly altered as regards industrial use. A bronze alloy with the proportion of $\frac{3}{1000}$ of phosphorus, sustains friction well, and can be indefinitely recast without appreciable loss industrially.—On the cure of hypertrophic elongation of the neck of the uterus by igneous utero-vaginal myotomy, by M. Abeille.—On the industrial preparation of nitro-glycerine, by MM. Boutmy and Faucher. (This note was in a sealed packet, deposited in August, 1872.) In the ordinary manufacture the reaction liberates much heat, which tends to decompose the nitro-glycerine formed. The authors first make sulpho-glyceric acid treating glycerine at 30° with three times its weight of sulphuric acid at 66°; and sulpho-nitric acid by mixing equal weights of sulphuric acid at 66° and nitric acid at 48°. Then these two acids are united, giving a mixture like this: glycerine, 100; nitric acid, 280; sulphuric acid, 600. The rise of temperature is then limited to 10° or 15°. The reaction is finished in about twenty-four hours. The nitro-glycerine forms in a distinct layer above the acids, from which it can be separated by decantation.—Report on experiments made, in several communes of Charente, with a view to destruction of phylloxera, by M. Boutin. To succeed well with sulpho-carbonate of potassium, alone or with water, or with coal-tarred sulphur carbonate, the operations should be done in October, November, or even December (if not too cold), then again from March till the end of May.—On a general proposition of the theory of conics, by M. Halphen.—On the effects of eddies observed in water-courses, by M. Bouquet de la Grye. If there be poured into a glass vessel first a dense liquid like aniline, then water, then oil, and the upper liquids be put in rotation with paddles, a central depression forms at the surface of the oil; a cone of the liquid descends in the centre, while a protuberance of niline rises from the bottom. A similar action of the eddies in rivers accounts for the raising and removal of sand, and the form assumed by the river's bed. And the movement of liquid threads in a river-bend may be compared to that in the vessel, taking as centre the successive points of the convex bank, and as border the concave part. There are vortices with horizontal axes also. The author thinks that by suitable dams, &c., the *vis viva* of the water might be utilised for deepening the channel.—On the laws of vibratory motion of tuning-forks, by M. Mercadier. The duration of the period of vibratory motion increases or diminishes with the amplitude. This variation, even for considerable amplitudes of 1 cm., is very small, and extends only to the fourth figure. If a certain limit, which may be fixed at 4 mm., be not exceeded, the duration of the period may be regarded as constant.—On the electrical apparatus of the torpedo, by M. Rouget. A histological description

FUNGUS DISEASE OF INDIA

The Fungus Disease of India: a Report of Observations. By F. R. Lewis, M.B., and D. D. Cunningham, M.B. (Calcutta: Government Printing Office, 1875.)

FEW questions are more perplexing than the relations of fungi to different diseases to which the animal world is subject. On the one hand the most exaggerated and ill-founded theories have been put forth, which have tended to cause the most senseless alarm, while on the other hand their agency has been altogether denied, or if at all allowed, restricted to subjects already in a depressed state of health, and therefore as merely availing themselves of a fitting nidus for their development. The truth probably lies between the two extremes, and if the analogy of the vegetable kingdom be allowed to have any weight, it is difficult, after what we know of the propagation of the potato-murrain by means of zoospores in perfectly healthy individuals, to deny the possibility of infection without a previous morbid state. The advocates, indeed, of these views, at once cut off all argument by the assertion that the potato-plant, by reason of long propagation by means of tubers, has become essentially unhealthy, but the same might be asserted of members of the animal kingdom subject to disease, as indeed is the case with that to which silkworms fall victims, by reason of inoculation with the spores of *Botrytis bassiana.* The real point, however, is whether even in unhealthy subjects, fungi merely find a proper nidus for their growth, or whether they may induce disease in these subjects, and no question in pathology can be conceived of greater importance. It at least seems quite certain that a gangrenous state of wounds may arise from the access of fungoid germs from the air, and that proper means to prevent their access, or to destroy their vitality, are effectual.

The work, therefore, which bears the title given above, is of unusual interest, relating as it does to one of the most formidable maladies to which the human frame is subject, and it demands very patient observation, as the authors have not only paid the greatest attention to questions of the kind, having had a special preparation for such investigations before entering upon their study, but, what is unfortunately of too great rarity amongst persons who have written on such subjects, are thoroughly acquainted with the nature of that part of the vegetable kingdom which is called in question.

It is not necessary here to describe the peculiar features of the disease, which would take us far beyond our limits, farther than to state that it appears under three different forms, in one of which black sclerotioid bodies of various sizes, from a grain of sand to a small walnut, excavate hollows in the bones, or are ejected with various sanious matters from the wounds, and it is to this form that the observations have a special relation. In the article in the *Intellectual Observer*, Nov. 1862, by the writer of this notice, which was founded on observations communicated by Dr. H. J. Carter, it is stated that the figure *d*, p. 256, represents the natural state of the red fungus, *Chionyphe Carteri*, springing from particles of the black fungus scattered over rice paste. It should seem, however, that there is some doubt about this as our authors deny that the Chionyphe[1] has ever been raised from the black fungus. It is at least certain that all attempts of our authors to raise it from the Sclerotioid mass have failed, and it is supposed that the Chionyphe was an accidental growth from macerated specimens of fragments of either the black or pink form of the disease. It is doubtful whether any great weight can be laid on the pink colour. Nothing is more common in this country than for pink spots to occur on paste or decaying fungi, and these pink gelatinous specks are capable of propagation, as is also the case with the bright blue specks which occur in similar situations, as I have myself proved, and of which I preserve specimens. The so-called blood-rain belongs to the same category. Unfortunately it has not yet been proved that these bodies are capable of development into higher forms. The real point is whether these sclerotioid bodies are really of a fungoid nature at all, a point which is worthy of mature consideration.

And here our authors very properly call attention to the fungoid forms which appear in the myeline of Virchow. The observations are so important that it is well to give them textually:—A development of myeline is especially prone to occur where portions of the fatty matter, roe-like masses, &c., freshly removed from an alcoholic preparation, are subjected to the action of liquor potassæ. The multifarious and highly complex forms of tubes, filaments, globules, and cysts, which may frequently be observed to become developed, shooting out and, as it were, growing from the globules and aggregations of fatty matter, are wonderful, and such that they could hardly be believed to owe their origin to any such process or material, were not their development distinctly traceable through all its stages.

"From the extremely organised nature of their appearance they are, as the accompanying figure will show, peculiarly liable to be mistaken for fungal growths, especially by those who are unused to the practical study of such bodies and to the various appearances presented by complex oily bodies, and it is necessary that very great caution should be exercised in the interpretations of such phenomena."

This is clearly of the utmost importance, and cannot be too thoughtfully considered. The calcospherites of Prof. Harting, the concretions of Mr. Raines, and the curious specimens of dentine exhibited at Norwich, in 1868, so similar to cellular tissue as to deceive the most instructed who were not acquainted with their orgin, belong to the same class of bodies.

We are not surprised, then, after these considerations, the futile attempts to raise the Chionyphe from the Sclerotioid bodies, and the mode of origin of the fungus in other cases, that our authors have arrived at the conclusion that the Fungus-foot of India is not due to any fungus growth.

The roe-like bodies which occur in the pale variety of the disease are shown to be fat in various modified forms; the pink particles were determined to be pigmented concretions, while the black masses consist of degenerated tissues mixed to a greater or less extent with black pigment and fungoid filaments. These fungoid filaments would not be coaxed by any treatment into the development of fruit, and their nature, therefore, must still remain doubtful.

---

[1] The genus Chionyphe, it should be observed, does not grow on snow, but on wheat, or other vegetables that have been buried under snow.

Our authors conclude that it is more reasonable to infer that localised spots in the tissues undergo a degenerative change into a substance peculiarly adapted to the development of filamentous growths, the origin of which, in situations where no spore could penetrate, must remain matter of perplexity.

M. J. BERKELEY

THE ADMINISTRATION OF PATENT LAWS IN ENGLAND

Abstract of Reported Cases relating to Letters Patent for Inventions. By T. M. Goodeve, M.A. Barrister-at-Law, and Lecturer on Applied Mechanics at the Royal School of Mines. (London: Henry Sweet, 1876.)

THE subject of the Patent Laws of this country which is now upon its trial, is one which largely affects the interests of scientific men in almost every branch of research, for in a great majority of cases a patent is the only channel through which the inventor of a good thing, which may confer inestimable benefits upon mankind, has any chance of being remunerated.

There is, at the present time, great diversity of opinion upon the question whether the Patent Laws should exist at all or be abolished, and there is also a diversity of opinion among men of science whether a scientific invention designed for scientific purposes ought to be patented, or freely given to the world. It is universally admitted, however, that some mode of rewarding the individual whose ingenuity and perseverance have enabled him to discover a new invention ought to be in existence; but, until some better system than that of patents is established the laws must be dealt with as they are. With regard to purely scientific inventions it is impossible to draw a hard and fast line between those useful alone to science and others upon which large commercial industries may be built. It often happens in the course of scientific research that an idea is struck upon, which, while aiding the immediate inquiry, is at the same time the solution of some great commercial problem, out of which fortunes may be made. The history of the science of Chemistry alone abounds with innumerable instances of the truth of this, and assuredly the original inventor ought to share in benefits derived from what could not have existed apart from his discovery.

The *principle* of patents is in itself good, because it provides that the reward of the inventor is regulated by and is proportionate to the utility of the thing invented, and to the amount of benefit derived from it by the community and, at the same time, that reward is at the expense of that portion of the public who use the invention, and not, as in alternative schemes, at the cost of the public at large. The carrying of that principle into practice, however, is beset with so many difficulties, and the administration of the laws relating to it is so very defective, that a patent which is worth anything, can only be maintained at the cost of endless litigation, which often swamps all possible profits, and with a few exceptions lands the inventor in a large sum out of pocket.

Much of this would be saved if inventors had a more accurate knowledge of the Patent Laws, and knew something of the principles upon which they are administered in the tribunals of the land. Many a patent is taken out for an invention which is legally disqualified from being the subject-matter of a patent, and every day letters of patent are being granted for things which have been invented and patented over and over again. They are never refused on this ground, and the mischief is not discovered until the expenses of an action at law have been incurred.

Prof. Goodeve's work, though not a treatise on the Law of Patents, gives to the reader a remarkably clear insight into that law and its administration, by enabling him to understand the reasons which must guide a court or jury in their decisions upon patent cases.

From the vast medley of reported cases scattered throughout the archives of the Courts, the author has made a selection of abstracts chosen with great judgment on account of the characteristic nature of the principles involved, and, by the omission of all matter extraneous to those principles, has put forward the real points at issue in a very prominent and instructive manner. In each case the essential pleadings are given, and the inventions are described as nearly as possible in the language of the specification. The claims are stated, with the evidence adduced in their support at the trial, and both the direction of the judge and the finding of the jury are given in a clear and condensed form.

Many of the cases quoted in Prof. Goodeve's book involve points of high scientific interest; and, apart from its obvious value as a work of legal reference, it will be found to be a useful handbook to the inventor, and not without some considerable interest to the general scientific reader.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*]

Sumner's Method at Sea

IN NATURE for August 24 you were good review, in very favourable terms, Sir William recently published book of tables for facilitating Sumner's Method of navigation. Since then you republished an attack on that method by the Astronomer Royal, which he made in the form of a letter to Prof. Stokes, after Sir William Thomson had communicated to the Royal Society the plan upon which his tables are based. Will you allow me, as one who took an active part in preparing Sir W. Thomson's book for publication, and who has had a good deal of practical experience of his method, to endeavour to reply shortly to the criticisms of the Astronomer Royal?

In publishing Sir G. B. Airy's letter, Prof. Stokes appended a note which was really a complete answer to the objections brought forward, and this was further enforced by remarks made by Sir W. Thomson in a second communication to the Royal Society (*Proc.*, June, 1871). As, however, the subject was but briefly treated in these communications, and the Astronomer Royal's letter has been republished at his own request, it may not perhaps be useless to go into the question in somewhat greater detail.

After stating the geometrical conditions under which the Sumner line, or *locus* of the ship's position is obtained from a single observation of altitude and time, the Astronomer Royal points out the very obvious truth that the accuracy of the position of the line depends on the accuracy with which Greenwich time can be reckoned from the ship's chronometers; that the Sumner line will have been drawn east or west of its true position according as the chronometer is slow or fast. He then adds:—

"And the question now presents itself, which uncertainty is the greater—the uncertainty of latitude, which it is the real object of this problem to remedy? or the uncertainty of the chronometric longitude, which must be used in attempting to find the remedy? I do not doubt the reply of every practical navigator, that the chronometric longitude is far more uncertain than the latitude; and if it be so, the whole method falls to the ground."

Now this passage can only mean that Sumner's Method, while correcting one uncertainty which exists in the ordinary plan of working out sights, introduces another and a greater uncertainty, and so does more harm than good. Unless it means this, the question which uncertainty is the greater is completely beside the point. The statement, however, is wrong in both particulars. Sumner's Method does not remove uncertainty as to latitude, it only limits and defines that uncertainty to the extent which the data allow, and it introduces no new uncertainty whatever. Every other method of working out an observation of altitude and chronometer time gives results which are uncertain as to longitude for just the same reason and to just the same extent as are those given by Sumner.

The ordinary usage, for which Sir W. Thomson desires to substitute Sumner's Method, and with which he contrasts it in showing the superiority of the latter, is to estimate, by dead-reckoning or otherwise, the latitude, and then to compound this information with that derivable from the observation so as to obtain a knowledge of the longitude, and thus be able to say that the ship is at such and such a point. Now this operation is mathematically equivalent to drawing separately the Sumner line for the observation, and an east and west line through the estimated latitude, and then taking as the position of the ship the point in which these two lines meet. The result obtained is precisely the same in both cases, but the second plan has the great advantage that each piece of information is exhibited on the chart independently of the other, so that either may be made use of before the other is acquired. As Prof. Stokes says, "it is hard to suppose that the mere substitution of a graphical for a purely numerical process could lead a navigator to forget that he is dependent upon his chronometer."

That Sumner's Method supplies a means of exhibiting for each observation "*precisely what that observation gives, neither more nor less*" (to use Prof. Stokes' words), is its chief though not its only claim to adoption. The ordinary practice of navigators produces, indeed, results which have a greater show of precision, but the show is fallacious, for the data are not there to warrant it; in Prof. Huxley's forcible phrase, it is a grinding of wheat-flour from peascods. The question in a word is this: Shall we prefer the ordinary usage, which quietly ignores two causes of uncertainty, to a method which, while it necessarily leaves one of these still untouched, keeps the other constantly in view, and limits it as far as the case admits? J. A. EWING

Sea Fisheries and the British Association

PROF. NEWTON has kindly sent me a copy of his address to the Biological Section of the British Association at their recent meeting at Glasgow. It contains much interesting matter; and like the addresses delivered by others to the same body in former years, was no doubt listened to with the respect due to the scientific attainments of the author.

It is with very great regret, therefore, that I feel it necessary to dispute the accuracy of some of Prof. Newton's ideas, and to point out that my friend made a very important mistake when, towards the close of his address, he spoke of "the falling off in our sea fisheries," and of the Royal Commission of 1863, to which I was secretary, having been appointed "to seek a remedy for it." It was not ascertained then that there was any falling off in our sea fisheries, nor is such known to be the case at the present time. I say this advisedly, because Prof. Newton was evidently not speaking of unsuccessful fishing in any one year owing to that frequent cause of failure—bad weather—but of a general decrease in the supply of sea fish. The Royal Sea Fisheries Commission to which he refers, was appointed in 1863, in consequence of the clamour of the line fishermen of Sunderland and of the adjacent coasts against the North Sea trawlers, who, it was alleged, were doing their best to ruin the fisheries by the wholesale destruction of spawn and young fish: but who, it appeared, after full inquiry had been made by the Commission, had committed the great crime of landing large quantities of fish in the local markets, and of underselling the local fishermen. The object of the gentleman who represented the complaints of the Sunderland fishermen to Parliament was specially to inquire into the effects of beam-trawling, and the Commission when at work was popularly known as the "Trawling Commission;" but the Government, finding a great deal of interest taken in the fisheries generally, thought it desirable to extend the inquiry into the state of all the sea fisheries around the United Kingdom, and it consequently became the most comprehensive investigation of the subject that had ever been made.

The following were the points the Commissioners were instructed to inquire into, as stated in the Commission:—

"1. Whether the supply of fish from the sea fisheries is increasing, stationary, or diminishing.

"2 Whether any of the methods of catching fish in use involves a wasteful destruction of fish or spawn, and, if so, whether it is probable that any legislative restriction upon such method of fishing would result in an increase in the supply of fish.

"3 Whether any existing legislative restrictions operate injuriously upon any of such fisheries."

The conclusion arrived at on the first point by the Commissioners—and I would call Prof. Newton's special attention to it—is thus stated in their report:—

"The total supply of fish obtained upon the coasts of the United Kingdom has not diminished of late years, but has increased; and it admits of further augmentation to an extent the limits of which are not indicated by any evidence we have been able to obtain."

It is desirable to call attention to the important fact that the above conclusion arrived at by the Commissioners was not based on newspaper reports—the common foundation of the frequent alarms about the sea fisheries—but on careful and laborious examination of the fishermen in their own towns and villages, of fishmongers, fishing boat builders, market and railway returns, and every kind of evidence that could be obtained which bore on the question of the supply of sea fish, and the condition of those persons who were dependent on it for their livelihood.

On the second point of the inquiry the conclusion was that any legislative restrictions on the methods of fishing would result in a decrease in the supply of fish.

And on the third point, the Commissioners stated that they found the existing regulations complicated, confused, and unsatisfactory; many regulations, even of late date, were never enforced; many would be extremely injurious to the interests of the fishermen and of the community if they were enforced; and with respect to these and others, the highest legal authorities were unable to decide where, and in what precise sense, they were operative.

As Prof Newton started under the false impression that the Commissioners were appointed in order to seek some remedy for a falling off in our sea fisheries, it is not, perhaps, surprising that he did not clearly apprehend the meaning of their conclusions, although I should have thought that anyone reading them with ordinary care could hardly fail to do so. He says: "That Commission reported in effect that there was nothing to be done with our sea fisheries but to leave them alone." There is a despairing tone about this which would be very depressing if an examination of the Report did not result in showing that the Commissioners deprecated any interference with our sea fisheries for the simple reason that their produce was not falling off, but was increasing. They recommended, however, the removal of all vexatious and useless restrictions, and they advised a strict enforcement of such regulations as would prevent the interference in particular cases of one kind of fishing with another kind, and as would conduce generally to the maintenance of order on the fishing grounds.

Such are the facts of the case; and I cannot help thinking that if Prof. Newton had given a little more attention to the subject before he delivered his address to the British Association, he would scarcely have expressed himself in the terms in which he did on that occasion. Such statements and opinions from a person in his position, and addressed to a body like the British Association, can hardly fail to have considerable weight with those who heard or read about them; but more practical mischief is likely to result when they are repeated to the fishermen themselves, by keeping them in a continual state of apprehension lest the Government should interfere with their work. Such was the very general fear around the coast when the last Commission began its work, and one of my most difficult and constant duties in connection with the Commission was to satisfy the fishermen that the desire of the Government was to promote the success of the fisheries by every means in their power, and to impose no restrictions or regulations upon them which were not clearly consistent with that object. I have neither time nor inclination again to deal with all the old arguments which year after year have been brought forward to show that our sea fisheries are being ruined. It is not quite two years since I entered at some length into the subject in my work on "Deep-sea Fishing and Fishing-boats," and the question is not one that can be discussed in a few lines, or even pages. But I may ask Prof. Newton how he reconciles his belief in a falling-off in the supply of sea fish with the recent considerable enlargement of Billingsgate Market, the continued immense fish traffic on the railways, and the large additions which have been made, and are now being made, to the capital invested in fishing-boats and gear? Brixham alone has added twelve new large trawlers, costing nearly 1,200*l*. each, to her fleet in the present year; and the shipwrights there were hard at work on several more for other stations when I visited the place last month. Prof. Newton rightly calls science to the aid of the sea fisheries, for there is still an immense deal to be learnt about the economy of fishes which may help the fishermen in their work. He makes no reference, however, to the important discoveries which have already been made by Professors Sars and Malm on the coast of Norway. The investigations of the former naturalist especially, carried on for several years, have resulted in showing that there need be little fear of disturbing the "spawning beds" of most of our edible sea fishes, as the spawn of almost all those in chief request is not deposited on the bottom, but floats during the whole process of development.

I will not enter into the question of destroying the balance of nature, on which Prof. Newton laid so much stress in his observations at Glasgow, because I believe we are all too ignorant of the conditions affecting it to be able to do more than theorise on the subject; but I would ask my friend, assuming he is correct in his belief that our sea fisheries are falling off, whether he has considered the probable effect on them and on the balance of nature, of the tens of thousands of additional gulls, guillemots, &c., which I hope will result from our sea birds being undisturbed during the breeding season, under the Sea Birds' Protection Act, of which he was such an earnest advocate?

I do not know on what evidence he grounds his belief in the decline of our sea fisheries: but I have no hesitation in saying, as the result of my inquiries during the last few years, that the average annual produce of those fisheries has considerably increased since the Royal Commissioners were engaged in inquiring into their general condition. Bad weather has had an important effect in some years in interrupting the fishermen's work; but fluctuations from such causes have continually occurred, and they will undoubtedly happen again.

E. W. H. HOLDSWORTH

Mr. Wallace and his Reviewers

I DID not intend to take any public notice of reviews or criticisms of my book on "Geographical Distribution"; Mr. Gill's letter, however, calls for a few remarks. I have first to thank him for pointing out the errors of a previous critic, and also for a list of *errata* in the account of North American fresh-water fishes. He very truly remarks, that had I been acquainted with ichthyology and its literature these errors might have been avoided; but he has overlooked the fact that I have twice stated (vol. i., p. 101, and vol. ii., p. 168) that the part of my work relating to fishes is, practically, a summary of Dr. Günther's Catalogue. The labour of going through such an extensive work for the purpose of extracting and tabulating summaries of the geographical materials it contains, was very great, and no doubt I have made some errors. Most of those indicated by Mr. Gill depend, however, either on differences of classification and nomenclature, or on additions to North American ichthyology since the date of Dr. Günther's work, and are therefore due to the plan of this part of my book, and not to oversight. Although possessing a tolerable acquaintance with the literature of ornithology, I had found the task of collating and combining the latest information into a uniform system of classification and nomenclature to be one which severely taxed whatever knowledge and literary ability I possessed. To have attempted to do the same thing in a class of animals which I had never studied would, I felt sure, have resulted in great confusion, and have been far less satisfactory and reliable than the course I have adopted. Had I been able to find any work giving a general account of the fishes of temperate North America, I should gladly have availed myself of it, but I do not gather from Mr. Gill's letter that any such work exists; and notwithstanding the great imperfection of the results (in the eyes of a specialist) as regards the fishes of the United States, I still think I exercised a wise discretion in confining myself to the vast mass of materials, classified on a uniform system, which Dr. Günther's Catalogue affords.

I may here add, that the "24 peculiar genera" mentioned by me are in addition to the "5 peculiar family types"—making together the "29 peculiar genera" referred to in the succeeding paragraph—so that the contradiction alluded to by Mr. Gill is only apparent.

ALFRED R. WALLACE

Dorking, October 30

Self-fertilisation of Plants

IN NATURE, vol. xiv. p. 475, I find an abstract of Mr. Meehan's paper on the "self-fertilisation" of *Browallia elata*. When I first saw this paper in the *Proceedings* of the Philadelphia Academy of Natural Sciences, I suspected that the observation was incomplete and the inference hasty. It is therein stated that the densely bearded connectives of the upper anthers completely close the tube of the corolla with a bearded mass; that "no insect can thrust its proboscis into the tube except through this mass; and if it has foreign pollen adherent to it, it will be cleaned off by the beard; furthermore, the very act of penetration will thrust the anthers forward on to the pistil [meaning stigma], and aid in rupturing the pollen-sacs [opening the anther cells?] and securing self-fertilisation." My inspection of the flower showed that the orifice of the tube was clearly pervious on the (morphologically) anterior side by a chink, which is nearly divided by a crust of the tube into two orifices, one exactly before each anther-cell; a hog's bristle, slightly moistened, on being thrust down these passages in a freshly open flower, and then withdrawn, was found to have the inserted part well supplied with adherent pollen, so that it was *not* "cleaned off by the beard," nor was it cleaned off by introduction into the orifice of a second flower.

As to self-fertilisation being brought about by the thrusting of the overhanging anthers down upon the stigma, this seems to be effectually prevented by the lodgment of these anthers in a pair of cap-like concavities at the back of the stigma, so as to keep them quite away from the actual stigmatic surface. It is obvious that if insects ever self-fertilise *Browallia* it is by carrying down upon their tongue or proboscis some pollen from the upper anthers; but in this operation, passing from flower to flower, they are quite as likely to cross-fertilise them. The blossoms are freely visited by *Hymenoptera* and *Lepidoptera* of various sorts. It is quite probable that the other cases of "self-fertilisation" brought forward by Mr. Meehan may equally bear a different interpretation from his own.

Cambridge, Mass., U.S.A.

Nitrite of Amyl

MR. GEORGE ABYARCH, of Cincinnati, asks of me through the columns of NATURE two questions concerning the nitrite of amyl, which I may briefly answer as follows:—(1) Nitrite of amyl has been used, and with considerable success, in the treatment of epilepsy, but its application can only be entrusted to a regular practitioner of medicine who understands its mode of action. (2) It has not as yet been proved to be of service in the treatment of paralysis.

B. W. RICHARDSON

CAPT. NARES'S REPORT[1]

H.M.S. *Alert*, at Valentia,
October 27, 1876.

SIR,—I have the honour to report in detail the proceedings of the Expedition since leaving Upernivik on July 22, 1875, as follows:—

The *Alert* and *Discovery*, one ship in tow of the other, left Upernivik, from which port I last had the honour of addressing you, on July 22, 1875.

A dense fog prevailing at sea I steamed to the northward, between the islands and the main land, experiencing clear and calm weather until arriving near Kangitok

---

[1] Communicated by the Lords Commissioners of the Admiralty.

Island, when the fog, stealing in from the sea, gradually obtained the mastery, and completely enveloped us. The numerous picturesque rocky islands and reefs in this sheltered labyrinthine passage are so incorrectly represented in the public charts that a pilot is at present a necessity. The one who accompanied us, an Esquimaux, informed me that many of the likely-looking channels are bridged across with sunken reefs, and from the many rocks we saw lying just awash directly in our passage, I have reason to believe his statement.

The large discharging Upernivik Glacier having only one outlet leading direct to the sea, its numerous icebergs of all sizes are collected in great numbers by the eddy tides and currents among the islets situated to the southward, and tend to keep the channels completely closed until late in the season; but when once open in July by some of the bergs grounding on rocks, and others, by their height above the flotation line, affording certain evidence of deep water, they assist rather than impede navigation during calm weather. On the morning of the 23rd, after an anxious night, passed with a dense fog and a strong tidal current in a narrow channel, in which we could obtain no bottom with 100 fathoms of line at a cable's length of the shore, and with the *Discovery* in tow, during a momentary clearance of the atmosphere, two Esquimaux in their kyacks were observed close to us. After consulting with them through Christian Petersen, Danish and Esquimaux interpreter, they volunteered to conduct us to an anchorage. On following them to the position they denoted, and obtaining no bottom with the hand-lead line at the main chains, I felt the bow of the ship glide slowly up on the ground. Through the fog we could then see that the land was within fifty yards of us. The Esquimaux had evidently not considered that our ships required a greater depth of water to float in than their own frail canoes. As it was nearly low water, and the tide still falling, I allowed the ship to remain quiet where she was, the *Discovery* still hanging to us by her towing hawser, and took advantage of the enforced delay by landing the ships' companies to wash their clothes.

The fog lifted slightly as the day advanced, and as the tide rose the ship floated without having incurred any strain or damage whatever. I then proceeded to sea, discharging the pilot, who was not to blame for our mishap, off the north shore of Kangitok, the outlying island of the group, after passing which the channel presents no difficulties.

Thinking that probably a distorted account of our getting on shore might reach Europe, at the last moment I wrote a hasty pencil letter to Capt. Evans, hydrographer, merely to point out how very unimportant the slight detention had been.

By 4 P.M. we had passed the Brown Islands with a sea perfectly clear of ice before and around us. Having given much study and consideration to the question, and a high and very steady barometer following a south-east wind, denoting that the calm settled weather we had lately enjoyed was likely to continue, I decided to force my way through the middle ice of Baffin's Bay instead of proceeding by the ordinary route round Melville Bay. Accordingly both ships proceeded at full speed to the westward, racing in company for Cape York, with only about a dozen icebergs in sight ahead, floating quietly on a calmly mirrored sea to dispute our passage. As we passed out from the land the fog gradually dissolved and revealed a magnificent and unique panorama of the ice-capped mountains of Greenland which give birth to the Upernivik Glacier, fronted by innumerable icebergs, and, at a long distance in advance, by the group of scattered black islets among which we had passed the previous night, and of which Kangitok is the northernmost.

At 1.30 A.M. of the 24th we ran into the pack at a distance of seventy miles from Kangitok. It consisted of open-sailing ice from one to three feet, and occasionally four feet in thickness. The floes were at first not larger than 250 yards in diameter, and very rotten, dividing readily, and opening a channel when accidentally struck by the ship. The reflection in the sky near the horizon denoted that while the ice was very open to the southward of us, it was apparently closer packed to the northward. About 6 A.M., when we had run thirty miles through the ice, it gradually became closer, and the floes larger, estimated as measuring one mile in diameter, and necessitated a discriminating choice to be made of the best channels. For fourteen hours, during which time we ran sixty miles, the ice continued in much the same state, never close enough to suggest the probability of a barrier occurring, and yet keeping the look-out in the "Crow's Nest" fully employed. After 8 P.M. the channels of water became decidedly broader and more numerous, so I gradually altered course to the northward, steering directly for Cape York, the ice becoming more and more open as we advanced.

At 9.30 A.M. of July 25 we sighted the high land north of Cape York, and at 11 o'clock, much to the astonishment of the ice quartermasters, who continually declared, "It will ne'er be credited in Peterhead," we were fairly in the "north water," and able again to think about economising coal, having come through the middle ice in thirty-four hours without a check; but it is my duty to add, with not a few scratches along the water-line.

In consequence of our having made a successful voyage through the middle it should not be too hastily concluded that a similar passage can always be commanded. The middle pack is justly dreaded by the most experienced ice navigators. Large icebergs and surface-ice, floating in water at various depths, when affected either by wind or an ocean current, move at different rates; hence, when in motion, as one passes the other, the lighter surface-ice, incapable of controlling its course, is readily torn in pieces by the heavy massive iceberg; therefore, a ship once entrapped in pack ice among icebergs, unless she has water space to allow her to move out of the way, is constantly in danger of being carried forcibly against a berg. On such occasions man is powerless, for he can take no possible means to save his vessel. Before steam-vessels were used for ice navigation the masters of sailing ships, being unable to take full advantage of a favourable calm, very wisely seldom ventured to force their way through the middle ice, and chose, in preference, the chance of delay in making the safer passage through Melville Bay, where, by securing their vessel in dock in the fixed land ice, they ran less danger of being nipped whilst forcibly detained by the channels through the ice remaining closed.

At the latter end of July with an open season, indicated by the main pack not being met with nearer than fifty miles from the land, in about latitude 73° 20′ and a continuous calm, to allow the northerly running current on the Greenland shore and the southerly running one on the western side of Baffin's Bay to open up the ice, I believe a passage can always be made by a steam-vessel; but, unless this favourable combination of circumstances is met with, so far as the scanty knowledge we at present possess enables us to judge, the passage must still be said to be doubtful.

Soon after sighting land and getting clear of the drift ice, the *Discovery* parted company to communicate with the natives at Cape York, while the *Alert* proceeded towards the Carey Islands. A vast collection of icebergs, many of them aground, were thickly crowded together off the Cape, and in lines parallel with the coast trending towards Conical Rock and Cape Atholl. In the offing they were less numerous, which I attribute to the southerly current which we experienced the following day on our passage to the Carey Islands, catching up and carrying with it to the southward those that drift out from the main body to the westward beyond the influence of the north-running current on the Greenland coast.

During the stay of the *Discovery* at Cape York the natives were communicated with through Christian Petersen, interpreter, and Hans the Esquimaux, but as the brother of the latter was absent on a hunting excursion for an uncertain period, Capt. Stephenson wisely gave up the hope of obtaining his services for the benefit of the expedition, and pushed on for the Carey Islands, where he joined company with the *Alert;* the two ships arriving there at midnight on July 26.

A depôt of 3,600 rations and a boat were landed on the south-east point of the south-east island, and a record deposited in a conspicuous cairn on the summit. The "Expedition" then proceeded, steaming with as much economy of coal as possible, northward through a calm sea, with bright clear weather. With the exception of the many scattered icebergs there was no ice in sight from the summit of Carey Islands. Passing between Hakluyt and Northumberland Islands, the ships were abeam of Cape Robertson, by 8 P.M. of July 27. Ice apparently fast to the shore, completely closed Inglefield Gulf, east of Cape Acland, but both entrances to the gulf were clear. At 8 A.M of July 28, five days and a half from leaving the anchorage of Upernivik, I had the satisfaction of seeing the "Expedition" at anchor near Port Foulke, with the entrance of Smith's Sound perfectly clear of ice, and none coming to the southward with a fresh northerly wind.

While Capt. Stephenson explored the head of Foulke Fiord to ascertain its suitability as a station for winter quarters for any relief vessel coming to our assistance, Commander Markham and myself proceeded in a boat to Littleton Island and Life Boat Cove, the scene of the wreck of the *Polaris.* The cache mentioned by Dr. Emil Bessels and Mr. Bryant of the "United States North Pole Expedition" as the depository of certain instruments and boxes of books was very readily discovered, but contained nothing. Articles of clothing and numerous small caches containing seal and walrus meat were scattered about all over the small peninsulas in the neighbourhood of the late winter quarters, and near the ruins of the house, but apart from each other and without any protection, were found four or five boxes, each covered with heavy stones to prevent the winds moving them, and having the lids secured on by a rope. Besides one thermometer, unfortunately not a self-registering one, they contained scraps of skin clothing, old mitts, carpenter's tools, files, needles, and many small articles of the greatest use to the Esquimaux, but apparently they had not been disturbed since the abandonment of the station. A few books were found in the different boxes, and a copy of the log, or the actual log itself, from the departure of the vessel from the United States up to May 20 the following year. No pendulum, transit instrument, or chronometer was found. Three skin boats left on the shore, weighted down with stones, were in fair order. The smallest one was taken for conveyance to Cape Sabine.

On returning to the *Alert* we landed at Littleton Island, and on the south-west brow erected a cairn, and deposited a notice containing a short account of the movements and prospects of the expedition up to that time. There was no ice in sight from a high station on Littleton Island; but the sportsmen roaming over the higher grounds on the mainland reported on their return that they had distinguished an "ice-blink" to the northward.

Port Foulke is at present the best known station for winter quarters in the Arctic regions. A warm ocean current, combined with the prevailing northerly winds, acting at the narrow entrance of Smith's Sound, keeps the ice constantly breaking away during the winter, causes an early spring and a prolific seal and walrus fishery. The moisture and warmth imparted to the atmosphere by the uncovered water moderates the seasons to such an extent that the land is more richly vegetated, and therefore attracts to the neighbourhood and supports Arctic life in greater abundance than other less favoured localities. In addition to this great advantage—of obtaining an ample supply of fresh meat—connected as its waters are with the "north water" off Cape York, it can readily be communicated with every summer without more than the usual risks attending Arctic navigation.

On the morning of the 29th the two ships sailed across the strait for Cape Isabella, with fine weather; but as we approached the western shore a snow storm worked its way over the land from the interior, and reached us just as we arrived at the Cape. As the weather was so thick that no one on board the ships, except those employed in establishing the cairn and small depôt of provisions, could see its position, and there being therefore no reason for delaying the *Discovery*, Capt. Stephenson proceeded. The cairn was built on the summit of the outer easternmost spur of the Cape, at an elevation of about 700 feet from the water. On the boat returning on board at 5 P.M., I steamed to the northward for Cape Sabine, the wind having died away, but the weather continuing misty with snow. By 8 P.M., when we were fifteen miles north of Cape Isabella, ice was sighted between us and the shore, and necessitated our keeping well out from the land.

Early in the morning of July 30, having run our distance for Cape Sabine I stopped steaming, and at 5 A.M., the mist clearing off, I observed the *Discovery* near the land apparently beset with a close pack five or six miles broad; no ice in sight to seaward. As I did not wish the two ships to separate, and the calm weather being favourable, I bored through the pack, which, although apparently close, opened sufficiently to admit of the slow progress of the ship until we gained the land in company with the *Discovery*, and secured the ships in a convenient harbour, named after Lieut. Payer, the successful and energetic Arctic traveller, two miles to the southward of Cape Sabine. A depôt of 240 rations was established on the southernmost of the islets in a convenient position for travelling parties, a cairn being built on the summit of the highest and outer one, and a notice of our movements deposited there.

The pack in the offing consisted of floes from 5 to 6 feet thick, with occasionally much older and heavier floes 10 to 12 feet thick intermixed with it, but all was very much decayed and honeycombed; still it could not be treated with the same impunity as the ice in the middle passage through Baffin's Bay.

I may here draw attention to the deceptive impressions inexperienced people naturally receive when from a lofty look-out station they observe a sea unbordered by ice. The distance from Littleton Island to Cape Sabine is only twenty-five miles. On a clear evening, from an altitude of 700 feet, with the land and horizon distinctly visible, no ice was in sight from the first-named place, and the prospects of the expedition as to attaining a higher latitude without trouble appeared to be precisely the same as when I looked over a boundless sea from the summit of one of the Carey Islands 100 miles to the southward, and yet the ships were twenty-four hours afterwards locked up by ice in a harbour near Cape Sabine. From Littleton Island the inexperienced observer would conclude that there was an open Polar Sea; from our present position he would as certainly conclude that his farther progress was for ever stayed, and that the sooner he looked for winter quarters the better.

The ships were detained at Payer Harbour for three days watching for an opening in the ice, getting under weigh whenever there appeared the slightest chance of proceeding onwards, but on each occasion being unable to pass Cape Sabine, were forced to return. Their resting-place proved to be an excellent station, well protected against the entrance of heavy floes, possessing a lofty look-out, and deep navigable channels to the north and south through which to proceed to sea immediately the ice opened with a favourable westerly wind. Being advantageously situated near a prominent Cape, where the tidal currents run with increased velocity, it is however subject to squally winds; but in icy seas during the summer, when awaiting the opening of the ice, they are rather an advantage than otherwise, striving as they do with the sea currents, which is to be the chief worker in removing the impediments to a vessel's advance.

Early in the morning of August 4, after several hours of light south-westerly winds, the main pack, while remaining perfectly close and impenetrable to the northward, moved off from the land to a sufficient distance to enable the ships to pass to the westward round Cape Sabine. In the hope of finding a passage on the western side of the island, of which Capes Victoria and Albert are the prominent eastern points, sail was immediately made, and we succeeded, with only one short detention, in advancing twenty miles along the southern shores of Hayes Sound, and securing the ships in a snug harbour. In the neighbourhood the sportsmen discovered a richly vegetated valley with numerous traces of musk-oxen and other game. Two glaciers coming from nearly opposite directions, which, instead of uniting in their downward direction, abut the one against the other, and maintain a constant warfare for the mastery, a never-ending grapple for victory, suggested the name of Twin Glacier Valley for the locality.

The ice in the sound was one season old, and decaying so swiftly that if not drifted away it would in a week's time present no impediment to the advance of a steam vessel. On August 5 the strong tides and a south-westerly wind opened a channel to the north-west, and we gained a few miles in advance; but not wishing to expend much coal, were finally stopped in the light pack. After remaining sufficiently long to determine that the flood tide still came from the eastward, although the ebb or east running tide was apparently the stronger of the two, I pushed the ship through the pack towards the shore, and with Capt. Stephenson ascended a hill 1,500 feet high. From this station, the appearance of the land giving no prospect of a channel to the northward, and, moreover, the westerly wind having set in in strength, which we expected would open a passage to the eastward of Cape Albert, we decided to bear up and return to the entrance of the Sound; accordingly the ships made a quick run under sail to Cape Albert, arriving off which the wind died away leaving the ice loosely packed. A clear space of water being visible along the shore of the mainland to the northward, and the coast between Cape Victoria and Cape Albert affording no protection, I ran the two ships into the pack under steam, with the hope of forcing our way through, but before midnight they were hopelessly beset; and the floe, to which the ships were secured at a distance of 100 yards apart, drifting rapidly towards an iceberg. Both ships were at once prepared for a severe nip, the rudders and screws being unshipped. At first the *Discovery* was apparently in the most dangerous position, but the floe in which we were sealed up by wheeling round, while it relieved Capt. Stephenson from any immediate apprehension, brought the *Alert* directly in the path of the advancing mass, which was steadily tearing its way through the intermediate surface ice. When only 100 yards distant the iceberg, by turning slightly, presented a broader front to the approaching ice, which then accumulated in advance of it to such an extent as to fill up the angle, and form, as it were, a point or bow of pressed-up ice, sufficiently strong to itself divide and split up the floe, and act as a buffer in advance of the berg; and this it did in our case most successfully, our floe breaking up into numerous pieces. The ship herself escaped with a very light nip, and, sliding past the side without accident, was finally secured in the water space left in the wake of the iceberg by the faster drift of the surface ice.

The next twenty-four hours were spent in a constant struggle towards the shore through the pack, which fortunately consisted of ice seldom more than 4 feet in thickness, with occasional pieces up to 12 feet thick, formed by the over-riding and piling up of ordinary floes, and then cemented together by a winter's frost; the worn down round-topped ice hummocks on these were from 6 to 8 feet above the water-line. The icebergs, evidently derived from inferior glaciers, were from 20 to 40 feet in height above water, and 100 yards in diameter.

Owing to the unsteady wind and the variable tidal currents we were unable to remain for long in any one pool of water—either the iceberg turned round and carried us with it to the exposed side, before we could change the position of the hawsers by which we were secured; or the pack ice, which was readily acted upon by the wind, drifting back the opposite way with any change, closed up the water space. Securing the ships in a dock in rotten ice in the presence of so many icebergs, was not advisable, and also would have carried the ships deeper into the pack to the southward. There was, therefore no alternative before me but to get up full steam and dodge about as best we could, taking instant advantage of every change in our favour. The ships were seldom separated for long, and now as on all other occasions, they mutually assisted each other. The *Discovery* was handled by Capt. Stephenson and her officers in the most masterly and daring manner, combined with great judgment, qualities essential in arctic navigation. She, as well as the *Alert*, ran not a few hairbreadth escapes. Once in particular when in following us through a closing channel between an iceberg and heavy floe-piece, before getting quite past the danger she was caught and nipped against the berg, and had it not been for a fortunate tongue of projecting ice would certainly have had all her boats on the exposed side ground away from her. Fortunately, the moving ice pushed her clear, much in the same manner as it had done the *Alert* the previous day.

Having less beam than the *Alert*, and a finer bow, with the very great advantage of an overhanging stem, the *Discovery* is better adapted for forcing her way through a pack. It will be difficult ever to efface from my mind the determined manner in which, when the bluff-bowed leading ship had become imbedded in the ice, which by her impetus against it had accumulated round and sunk under her bows, and a great quantity by floating to the surface again in her wake, had helplessly inclosed her abaft, the *Discovery* was handled, when advancing to our rescue; having backed some distance astern, for the double purpose of allowing the *débris* ice from a former blow to float away and for the vessel to attain distance sufficient for the accumulation of momentum with which to strike a second, coming ahead at her utmost speed she would force her way into the ice burying her bows in it as far aft as the foremast, the commanding officer on the bowsprit, carefully conning the ship to an inch, for had the ice not been struck fairly it would have caused her to cannon off it against ourselves with much havoc to the two. From the moment of the first impact the overhanging stem necessarily caused the ship's bow to rise 3 or 4 feet as she advanced from 12 to 20 feet into the solid floe and imbedded herself before the force of the blow was expended, and as the ship's way was stopped, the overhanging weight, by settling down, crushed the ice down still further ahead. Frequently on these occasions her jib-boom was within touching distance of the *Alert's* boats! But after a little experience had been gained, such confidence had we in each other that there was not the slightest swerving in any one. Floes up to 4 feet in thickness, and in a soft state, that is melting, not freezing, may be charged with advantage, thicker or harder ice had better be left alone. It speaks well for our chronometers, and the manner in which they are secured, that their rates were little effected by the frequent concussions on this and on many after occasions.

By 8 A.M. on the morning of the 8th we had succeeded in reaching the land water off Cape Victoria, having sustained no more serious damage during this severe trial than sprung rudder heads, consequent on the frequent necessity of going full speed astern; all heartily glad to be out of the pack ice. The two islands marked on the chart, on the authority of Dr. Hayes, as existing in the entrance of Hayes Sound are, as originally represented by the present Admiral Inglefield, in reality joined; the three capes named by the latter, north of Cape Sabine, are very prominent headlands, and readily sighted from a ship's deck from any position north of Littleton Island. There is no sign of an inlet along the very slightly indented coast line between his Cape Camperdown and Cape Albert. His Princess Marie Bay is the inlet north of the land in the middle of the sound, but whether that be an island or a peninsula remains to be determined; and his Cape Victoria is evidently one of the headlands on the present Grinnell Land.

It is necessarily an unthankful office to find fault with our predecessors; but navigators cannot be too careful how they remove from the chart names given by the original discoverers, merely because during a gale of wind a bearing or an estimated distance is a trifle wrong; and when the corrector or improver is also himself considerably wrong, and in fact produces a more unreliable chart than the first one, he deserves blame. The names given to the headlands undoubtedly discovered by Admiral Inglefield should not have been altered by Doctors Kane and Hayes, each of whom published very misleading delineations of the same coast.

It is as yet uncertain whether Hayes Sound is a channel or not. The flood tide coming from the eastward, the apparent continuity of the western hills, and the absence of berg pieces or heavy ice high up the sound, would lead to the supposition that it was closed; but considering the general configuration of the neighbouring land and the fact that the ebb or east running tidal current was stronger than that during the flood—but this the westerly wind might have occasioned—and the numerous Esquimaux remains which are usually found in channels, there seems no reason why we may not reasonably expect the existence of a narrow opening leading to a western sea. The very decayed state of the ice would be the natural result either from strong tidal currents in a long fiord or the increased strength of the ebb tide occasioned by an set from the Polar Sea.

On passing what is called on the chart Cape Victoria, Commander Markham landed to ascertain the state of the ice, but a very thick fog and snowstorm coming on he was obliged to return. The ships were secured to the floe in Princess Marie opening which consisted of the last season's ice which had not cleared out: it was very much decayed but sufficiently strong to prevent our forcing our way through it—and in fact when pressing in with the flood time it became so compact that at one time the ship was in danger of being driven on shore. At high water it opened and we succeeded in crossing the bay and securing the ships to the land ice in Franklin Pierce Bay on the southern shore of Grinnell Land.

On the morning of August 9, after depositing a record in a small cairn erected on a spur of the limestone hills, 200 feet above the sea, on the west side of the bay, one and a half miles east from Cape Harrison, we gained three miles of easting; but, being unable to round Cape Prescott, were compelled to make the ships fast to an extensive floe extending from that cape to Norman Lockyer Island, which stopped all further progress. Franklin Pierce Bay, which is about three miles broad and two and a half deep, and in which we found an unbroken smooth floe of one season's ice, is protected from any heavy pressure by Norman Lockyer Island and the Walrus Shoal, situated one mile further to the eastward; it is therefore a fit position for winter quarters. But, as far as we could judge during our short stay, there is very little game procurable in the neighbourhood. The shoal was so named in consequence of the numerous ancient remains of Esquimaux found on the island, who, by the number of bones found lying about, had evidently subsisted principally on these animals. At present this neighbourhood may be considered as the northern limit of their migration, only a very few having been seen farther to the north. The comparatively sluggish tidal motion at the entrance denotes that the coast lies out of the main run of the stream, and if so, Princess Marie opening will probably prove to be merely a deep inlet. In the extended basin of Smith's Sound the southerly current and the tidal streams run in a direct line between Cape Frazer and Cape Isabella, producing eddies and accumulating the ice in any open water space on either side of that course.

August being proverbially a calm month in the Arctic seas, and the western mountains protecting the coast from winds blowing off the shore, the ice is inclined to hug the land, and, except during strong westerly winds, a large amount of patience must be exercised by any one striving to advance to the northward. The pack in the offing in the main channel consisted principally of old floes which did not clear out of the sound during the previous season, mixed with light one-season ice, formed in Kennedy Channel and its numerous bays, and in Hall's Basin. Amongst these were scattered numerous icebergs discharged from the Humboldt Glacier, and the few smaller ones on the eastern shores, and here and there a heavy blue-topped hummocky floe of ancient ice from the Arctic basin, but of unknown thickness. By the scarcity of these the main drift of the northern ice is apparently in some other direction.

During the fortnight we were delayed in this neighbourhood, in the middle of August and the height of the Arctic summer, a constant watch was kept on the pack, and as often as possible from high elevations, from which we were able to distinguish even the eastern shore, with its glacier and heavy barrier of fringing icebergs. Although small openings were seen occasionally, I am satisfied that north of Cape Sabine it was at no time navigable to the smallest extent, and that any vessel which endeavoured to force a passage through the midd ice here, where it is drifting steadily towards an eve narrowing opening, as many have succeeded in doing the more open sea of Baffin's Bay, would decidedly be beset in the pack and be carried with it to the southward.

We were delayed near Walrus Shoal for three days, unable to move more than a mile in any direction, until August 12, when, during a calm, the ice set off shore with the ebb tide, and allowed us without much trouble to steam past Cape Hawks, and between it and Washington Irving (or Sphinx) Island—a very conspicuous landmark—but here the ice prevented any further movement, the flood tide closing in the channel by which we had advanced. A large depôt of 3,600 rations of provisions was landed on the northern side of Cape Schott, and a notice of our progress deposited in a cairn on the summit of Washington Irving Island. Two cairns were found there, but they contained no documents, and were much too old to have been built by Dr. Hayes in 1866, the only time any traveller has journeyed past the position.

On the western shore of Dobbin Bay there is no shelter obtainable, and the tides run with much greater rapidity than off the coast farther to the westward. During the next ebb tide, August 13, after blasting a passage through a neck of ice, I succeeded in conducting the ships to the eastern shore, and docking them in an extensive floe four miles north-west of Cape Hilgard. A mile north of our position was an island, having a channel half a mile broad between it and the eastern shore of the bay, named Prince Imperial Island. The land ice which had not broken out this season extended from the island in a westerly direction across the bay. Several small icebergs were frozen in at the head of the bay, where there are some large discharging glaciers named after the Empress Eugenie. The land, as far as our explorations went, was very bare of game, and not well vegetated. A floe of last season's ice was observed in the bay, between Cape Hilgard and Cape Louis Napoleon, but off each of those headlands the piled-up ice foot denoted very heavy recent pressure from the eastward.

On the evening of August 15, after considerable labour, we succeeded in blasting and clearing away a barrier which separated the ships from a water channel leading beyond Cape Louis Napoleon, but so narrow was the channel that, notwithstanding the extreme care of Capt. Stephenson, the *Discovery* took the ground for a few minutes whilst steaming between the ice and the shallow shore. By 8 A.M. of the 16th we had advanced to within five miles of Cape Frazer, but here we again met with a block. Calm weather and spring tides caused much and constant movement in the ice, the main tendency being to drift to the southward at the rate of about five miles a day.

The character of the pack had changed considerably, few icebergs were seen that were not aground, and the floes consisted principally of old hummocky pieces pressed together, of from 12 to 20 feet in thickness, the surface being studded over with worn-down hummocks of a blue bottle-glass colour, which denotes great age. In such ice it was impossible to cut into dock on account of the time it would occupy, even had we been provided with saws of sufficient length. Our only possible safety lay in keeping close in shore of grounded icebergs, but in doing so the two ships were obliged to separate. The *Alert* securing to one, and the *Discovery* forcing herself in between three smaller ones farther in shore.

On the two following days, during which the ice continued to drift to the southward and westward, the constant movement of the heavy floes, nipping together with great force, like the closing of a gigantic pair of scissors, between which, if once caught, the ships would have been instantaneously crushed, caused much anxiety, and necessitated constant watchfulness and much labour on the part of the officers and crew; and all were much distressed at losing three or four miles of the ground previously gained. The rudders and screws were constantly being shipped and unshipped, the midship boats were obliged to be turned inboard, on account of the ice touching their keels, and steam, when not in use, was always kept ready at twenty minutes' notice. Beyond wrenching the rudder-head, no serious damage occurred. On the 19th, the highest spring tide, the ice near us became more open; and from a high station on Mount Joy I saw that we could at least regain our lost station, and might get further north. Knowing that this was our last chance during the present tides, and until the strong westerly winds set in, and the pack having opened for the first time, I risked boring my way into the pack for two miles, and by doing so entered a channel round Cape Frazer which had long been considered as one of the most difficult milestones to pass on our passage north. By 9 P.M., after a few hours' delay during the flood tide which brought the ice inshore again, we were fairly in Kennedy Channel, secured to a floe off Cape John Barrow; only two days later in the year than when the *Resolute* was blown out of winter-quarters at Melville Island, in 1853, and with a fortnight of the navigable season still before us. Between Scoresby Bay and Dobbin Bay there is no protection obtainable except inside grounded icebergs; none of the shallow bays are deep enough to shelter a ship from the pressure of heavy ice.

Soon after midnight the ice moved off shore, opening a passage, and again allowed us to proceed, the water spaces becoming more frequent and larger as we advanced northward. Passing the mouth of a large bay about ten miles deep, after making a very tortuous course through the ice and many narrow escapes of being driven to the southward again in the pack, we reached what we supposed to be Cape Collinson, the second of two capes to the north of the large bay, which must be intended to be represented on the chart as Scoresby Bay. But as Cape Frazer is placed eight miles and Scoresby Bay twenty miles too far north, and the rest of the western land very incorrectly delineated on the charts, it is difficult to say where we arrived, and yet for the present it is necessary for me to describe the advance of the expedition by reference to the published charts. I shall therefore continue to do so with an occasional necessary reference to our correct latitude.

Between Cape Collinson and Cape McClintock, the north point of Scoresby Bay, is a slight indentation in the coast from half to three-quarters of a mile in depth, but affording no protection. North of Cape Collinson the land trends slightly to the westward, and about three miles north of the Cape turns sharp to the west, forming Richardson Bay, which is much deeper than represented, probably four miles broad and six deep. A heavy iceberg firmly aground two miles from the land in the shallow bay north of Cape Collinson, which had evidently never moved this season, prevented a compact floe from floating off shore. The same iceberg caught all the ice that streamed down the west coast and round Richardson Bay, guiding it out towards the south-east, away from Cape Collinson, off which, and between it and the iceberg, was navigable water. In this pool the two ships were secured, watching for an opportunity to get north, and during the forced delay employing our energies in trying, by blasting, to unlock the land ice from the berg, and let it drift south, with the hope of releasing the ice to the northward; but perhaps it is fortunate we did not succeed, as by doing so, if the ice in the offing had not opened at the same time, our principal protection might have been lost, the iceberg itself being too small to form a pool under its lee sufficiently large for both ships, even had it been for one. A depôt of provisions was landed at Cape Collinson for our future travellers bound to the southward along the coast. The current was observed to run with greater rapidity to the southward than in the broader part of Smith's Sound. During each flood-tide about five miles of ice drifted past us; for four hours of the ebb it remained stationary; thus about ten miles of ice drifted south daily, adding to the accumulation in the basin of Smith's Sound, unless, as is probable, it is carried as quickly into Baffin's Bay through the southern entrance. On the north side of each point on this shore the ice had piled up a wall-like barrier from 20 to 30 feet high, but elsewhere there was not much display of pressure.

On the morning of August 21, the water channels in the middle of the straits looking very inviting, we made a start at the top of high water, but were led by the ice so much out from the land that I returned to our friendly protecting floe and iceberg until the next tide, first endeavouring to clear the nip of one against the other by ramming; but finding that it would cost too much in coal and shake of the ship to clear it completely, and too much powder to blast it away, I gave up the attempt, after consultation with Capt. Stephenson, and considering that the constant open channels in the offing denoted more water farther off. The two ships started again at 9 P.M., just before low water, and after a troublesome passage through about three miles of close heavy floe pieces, we passed into open leads of water, extending to the north-east up the straits. A bitter northerly wind, accompanied with mist and snow, freshening at the same time, carried the ice with great rapidity to the southward, and obliged us to beat to windward under steam and fore and aft sails, tacking frequently to avoid the heaviest streams of ice. After this snowstorm the land remained covered with snow for the season.

By noon of the 22nd, after buffeting against a strong breeze, we succeeded in weathering the northern headland of the largest bay on the west coast, named on the latest charts Carl Ritter Bay, but agreeing by latitude and relative position with the neighbouring land on the north part of Richardson Bay. In this part of the channel there was very little ice, but three or four miles further north a heavy pack extended across towards Crozier Island, and obliged us to proceed in that direction. In the evening, the wind lulling, I took in the fore and aft sails, and steered through the most open channels to the northward, passing to the westward of Franklin Island, and at midnight we were abeam of Hans Island, with perfectly clear water between us and the eastern land; but streams of ice prevented our approaching the western shore. No deep inlet answering to the Carl Ritter Bay of the charts exists in its given latitude. Steaming to the northward, I endeavoured to close the western shore south of Cape Cracroft, but the ice prevented our doing so, and forced me to bear up to the eastward for Cape Bryant, passing which I found the pack extending across from Cape Morton and Joe Island to Cape Lieber, with a south-westerly wind constantly adding to it by driving more ice to the northward through Kennedy Channel. The *Discovery* then landed a depôt of 240 rations at Cape Morton for use of any travelling party exploring Petermann Fiord, and the ships beat back to Bessels Bay, in the entrance of which we obtained a sheltered anchorage to the north of Hannah Island.

On the 24th, the south-west wind still continuing, which I knew would open the ice on the western shore of Hall's Basin, I ascended Cape Morton. At an altitude of 2,000 feet it was perfectly calm, with a clear sky. The prominent capes of the channel were clearly visible—Cape Union seventy miles distant, and Cape Sumner fifty miles, the one locking in beyond the other to within five degrees. All the west coast of Kennedy Channel, up to Cape Lieber and Lady Franklin Sound, was clear of ice, with navigable water through the ice streams in the middle of the channel far to the northward. From Joe Island to the north, and east to Polaris Bay, the ice was clearly packed, but between Cape Lupton and Beechey was more open. Hurrying to the boat the ships were signalled to get under way, and we ran quickly to the northward across the channel under sail. Five miles north of Cape Lieber the pack obliged me to enter Lady Franklin Sound, on the northern shore of which an indentation in the land gave promise of protection. On a nearer approach we discovered a large and well-protected harbour inside an island immediately west of Cape Bellot, against which the pack ice of the channel rested. Here the ships were secured close to the shore on the morning of August 25.

On entering the harbour we had the satisfaction of sighting a herd of nine musk-oxen, all of which were killed; our joy at the good luck of the sportsmen and ourselves being greatly increased by the news that the vegetation was considerably richer than that of any part of the coast visited by us north of Port Foulke, the Elysium of the Arctic regions. Finding that the harbour was suitable in every way for winter quarters, and the abundance of the spare Arctic vegetation in the neighbourhood giving every promise of game being procurable I here decided to leave the *Discovery*, and to push forward with the *Alert* alone.

Owing to our high northern position, although the sun was still above the horizon at midnight, its altitude at noon was too low to affect the temperature much, consequently, after August 20 the temperature of the air remained steadily below freezing point for the winter, and the young ice was forming at midday much earlier than it does in more southern latitudes. Notwithstanding this, Arctic navigation depends so much upon the wind, that I considered that the transient Arctic season of twenty days' duration was still at its height. The ice in Robeson Channel was well broken up, moving up and down the strait with the change of tide, and only waiting for a wind to open a passage along shore.

Having strengthened my crew by embarking Lieut. Wyatt Rawson and seven men belonging to the *Discovery*, forming one travelling sledge party, on the morning of August 26 the two ships forming the expedition, the officers and crews of which had worked so harmoniously and successfully together, separated; those embarking in one, if the published charts and the statements of our predecessors proved correct, having the cheering feelings of in all human probability successfully completing the chief task assigned us, but the others, although elated at the prospects of their comrades and partaking generally in the inspiriting feelings, having a desperate fight to conquer the sensation of being left behind to play what they could not but consider a secondary part in the general programme.

On arriving at the entrance of the harbour the main pack was found to have closed in against the shore and completely filled up Lady Franklin Sound, some small floes streaming rapidly into Discovery Bay. In endeavouring to keep the ship clear of these, she touched the ground at the top of high water and hung there for half an hour, when, fortunately, by lowering the boats and lightening the ship a little, she floated again without damage. During the afternoon, at low water, the pack, which, apparently uninfluenced by wind, had been moving to the southward the whole day, but fastest during the flood tide, drifted slightly off the land. Immediate advantage was taken of the welcome opening which enabled us to proceed north, but on reaching Point Murchison, the pack extending completely across the strait, prevented all further progress; there was therefore nothing for it but to return to "Discovery Harbour," where the ship was again secured at the entrance ready to advance at the first opportunity.

On the 27th we experienced very light north-east winds. The ice in the channel continued to move to the southward, except during the height of the ebb tide, when it was either stationary or set slowly northward, but not sufficiently so to open a navigable passage, although just before high water it appeared so ready to move that I was induced to recall the skating parties to the ship and keep the steam up. On the 28th the ice was decidedly more open, and we were just about to move at 11 A.M., the commencement of the north running tide, when a thick fog enveloped us, and, hiding everything at more than twenty yards distance, effectually prevented our moving. Later in the afternoon it cleared off, but it was now low water, and on trying to move the ship I found that, although afloat, she was within a basin, surrounded on all sides by a raised embankment of mud, so, with the tantalising prospect of an open channel before us, we were forced to remain until the rising water enabled the lightened ship to pass over the obstacle. Hoisting up the boats and signalling a final "good-bye" to the *Discovery*, we succeeded in advancing to within a mile of Cape Beechey, fifteen miles north-east of Discovery Bay, when, in a tussle with a heavy floe-piece, the rudder-head—which had been badly sprung some days before—became so injured that the rudder was nearly useless; at the same time the pack was sighted pressing tight in against the cape on the northern side; I therefore secured the ship inside some grounded ice and shifted the rudder. While waiting at this part of the coast the sportsmen were fortunate enough to capture three more musk-oxen, a very welcome addition to our supply of fresh meat.

On the 29th the pack remained closed in to the northward of Cape Beechey until noon, when, at about the time of high water, from the summit of the cape, I observed it opening. The ship was immediately signalled to advance, and, picking up my boat on the way, we succeeded in reaching Lincoln Bay, but not without having to run an exciting and rather anxious neck-and-neck race with a heavy floe, which setting in towards the beetling precipitous cliffs of Cape Frederick VII., forming the south point of the bay, threatened to prevent our progress. At the entrance of Lincoln Bay, which otherwise is much exposed, some very heavy floe-bergs were aground on a bank, and they must to a great extent keep heavy ice from forcing its way into the bay during a south-easterly wind, in which direction the bay is perfectly open. The head of the bay, which appeared from the distance to be well vegetated, was filled with pack ice consisting of numerous small floe pieces less than a quarter of a mile in diameter, intermixed with "rubble," or "boulder" ice, now all cemented so firmly together with this season's frost that we had great difficulty in clearing away a dock for the ship.

On the 30th a depôt of provisions of 1,000 rations, for the use of travelling parties, was landed on the north shore of the bay. Soon after high water, the ice having opened out considerably, we proceeded to the northward; but, in doing so, some large floe pieces of unusually heavy ice obliged me, much to my regret, to stand out some three miles from the land, thereby risking the ship being beset in the pack which I was most anxious and careful to avoid happening. On all occasions of viewing the ice in Robeson Channel, since it was first seen from Cape Morton, I had invariably noticed lanes of water stretching south-east and north-west across the channel from about Cape Lupton on the Greenland shore, to Cape Frederick VII. on the west side, due probably to this being the narrowest part or neck of the channel, and the ice jamming across the narrowing space north and south of it, according to the direction of pressure. Consequently, when at 3 P.M. the ice prevented any farther advance, observing many pools of water near us, and having two hours of the north-running tide favoured by a light air still due, instead of returning to the safety of Lincoln Bay, I waited at the edge of the pack, in the hope of its opening. But in this I was disappointed, for at 4 P.M., having just sufficient warning to enable me to pick out the safest-looking place near us, that is, to get as far away as possible from the heavy ice, it completely encircled the ship, and she was hopelessly beset in a very heavy pack, consisting of old floes of 80 feet in thickness, and from one to four miles in diameter, the intervals between them filled with broken-up ice of all sizes, from the blue-ice rounded hummocks which were sufficiently high above the water-line to lift the quarter boats bodily as they passed underneath, whilst grinding their way along the ship's side, down to the smaller pieces which the previous nipping together of the heavy floes had rounded and polished like the boulders and pebbles in a rapid river. Intermixed with the pack, fortunately for us, was a vast collection of soft pats of sludge-ice formed during the last snowfall: this, if squeezed together before it is properly hardened into ice, forms into plate-like masses with raised edges, each piece, whenever moved, assisting to round its neighbour.

Since meeting the ice off Cape Sabine I had noticed a gradual but considerable change taking place in the appearance and formation of the floes. The heaviest that we first encountered were not more than eight or ten feet in thickness. Off Cape Frazer were a few more ancient pieces, estimated at the time as being twenty feet thick, but we now know that that was far short of the correct measure. But up to the present time, when the main pack consisted of heavy ice, I had failed to realize that, instead of approaching a region favoured with open water and a warm climate, we were gradually nearing a sea where the ice was of a totally different formation to what we had ever before experienced, and that few Arctic navigators had met, and only one battled with successfully; that in reality we must be approaching the same sea which gives birth to the ice met with on the coast of America by Collinson and McClure, and which the latter in 1851, succeeded in navigating through in a sailing vessel for upwards of 100 miles, during his memorable and perilous passage along the north-west coast of Banks Land, from Prince Alfred Cape to the Bay of Mercy, but there sealed up his ship for ever; which Sir Edward Parry met with in the same channel in 1820, but with the more difficult task before him of navigating against stream and prevailing wind, was forced to own conquered even him and his experienced companions; which, passing onwards to the eastward down McClintock Channel, beset, and never afterwards released, the *Erebus* and *Terror* under Sir John Franklin and Captain Crozier; and which, intermixed with light Spitzbergen ice, is constantly streaming to the southward along the eastern shore of Greenland, and there destroyed the *Hansa* of the German Arctic Expedition.

As our only hope of pushing north against the general set of the current, to say nothing of the extreme hazard of remaining in such a pack, consisted in regaining the shore, both boilers were lighted and full steam kept ready, in order to take immediate advantage of any opportunity that might occur. During the night, at the top of high water, the pack, which previously had been drifting in a compact body to the southward, eased a little near the edge of the large and deep floating floes, in consequence of a difference in the force of the surface and under-current; but before we were able to clear away a space of water at the stern sufficiently large to enable the rudder to be shipped, the ice closed, and obliged us to dismantle again. At the full height of the ebb current the pack again tried its best to open, but with the same result.

Fully expecting a change at low water, with much labour a working space was cleared under the stern, but owing to the spare rudder being very badly balanced we nearly lost our opportunity. At last, with the same momentary slacking of the ice pressure as occurred at the top of high water, with a greater pressure of steam than had been exerted even during the official steam trial, the ship commenced to move; when, by advancing and retreating, a water space was gradually formed in which the ship could gain momentum, and at last we pushed our way bodily into ice not quite so close, and succeeded most providentially in reaching the shore in Lincoln Bay. Had we been delayed another five minutes the ship would have been caught in the pack during the heavy gale which set in from the south-west the same evening, and continued for two days; and which, in fact, by forcing the pack to the north-east, out of the Robeson Channel, enabled the ship to pass Cape Union without any trouble.

During the late struggle, as well as on many previous occasions, it was noticeable how futile the efforts of the crew were to clear away the ice on the bow or quarter which impeded the movement of the ship, compared to the enormous power exerted by the ship when able to ram her way between the pieces even at ordinary speed. Thus steamers are enabled to penetrate through a broken-up pack which the old voyagers, with their sailing vessels, necessarily deemed impassable. At the same time there is a limit to the risks which are advisable to be run; no ship has yet been built which could withstand a real nip between two pieces of heavy ice.

On the afternoon of August 31, shortly after the ship was secured in her former position to the firm ice in Lincoln Bay, the wind gradually freshened from the south-west, blowing slightly off the land, accompanied with a snow-storm and a threatening appearance of the weather. So far as we could distinguish through the snow, the main pack was driven by the gale to the northward up the channel, but knowing that it would take some hours to produce a navigable passage past Cape Union, I waited until the morning of September 1, when with steam at hand ready if requisite, we passed up the straits, running before a strong gale 9½ knots an hour, between the western shore and the pack, which was driving quickly to the northward, at about three miles distance from the land. By noon, having carried Her Majesty's ship into latitude 82° 24′ N., a higher latitude than any vessel had ever before attained, the ensign was hoisted at the peak. On hauling to the westward at the northern entrance of Robeson Channel, we lost the wind under the lee of the land, and were obliged to furl sails and proceed under steam; at the same time the breadth of the navigable water channel was much contracted, until off Cape Sheridan the ice was observed to be touching the shore.

In Robeson Channel proper, except where the cliffs rise precipitously from the sea, and afford no ledge or step on which the ice can lodge, the shore line is fronted at a few paces distance by a nearly continuous ragged-topped ice wall from fifteen to thirty-five feet high. It is broken only opposite the larger ravines, where the soil carried down by the summer flood has, by accumulating, shallowed the water sufficiently to catch up the drifting ice as it passes, and form a line of more isolated ice hummocks. Here the continuity of the ice wall is occasionally broken. But on leaving Robeson Channel, immediately the land trends to the westward, the coast line loses its steep character, and the heavy ice is stranded at a distance of 100 to 200 yards from the shore, forming a fringe of detached masses of ice from 20 feet to upwards of 60 feet in height above water, aground in from eight to twelve fathoms water, and except where the coast is shallow extending close into the beach line. The average measurement of the ice in thickness as it floated is 80 feet, and it always breaks from the salt water floe of which it originally formed a part in pieces of slightly greater dimensions in horizontal measurements. On finding the ice close in at Cape Sheridan, having made good 25 miles of northing since leaving Lincoln Bay in the morning, my only alternative was to secure the ship inside this protecting barrier of ice, where she was accordingly placed during the afternoon, and a depôt of provisions of 2,000 rations established for the use of travelling parties. The weather remained thick until the evening, when I obtained a good view from a station about 300 feet above the sea level. The coast line continued to the north-west for about thirty miles, forming a large bay bounded by the United States' range of mountains—Mounts Marie and Julia and Cape Joseph Henry, named by the late Capt. Hall, are so conspicuous that it was impossible to mistake their identity although more than thirty degrees out in bearing on the chart. No land was to be seen to the northward although our wishes leading to the thought, we still hoped that the heavy clouds in that direction might hide it from our view. But considering the character and movement of the ice I was reluctantly forced to admit that it gave convincing proof that none existed within a reasonable distance, and that we had arrived on the shore of the Arctic Ocean finding it exactly the opposite to an "Open Polar Sea." The pack ice extended close in to Cape Sheridan and the shore to the westward of it, a pool of water being noticed on the east or lee side of each projecting point in the bay which the intervening ice effectually prevented our thinking of reaching. To the eastward the channel by which we had advanced was completely blocked by the return of the ice, and the ship, although fairly protected, was thoroughly embayed by the pack. The last snowfall had covered the land completely to a depth of from 6 to 12 inches and the low sloping hills formed anything but a cheering landscape.

During the night the wind again freshened considerably from the south-west, and in a squall carried away the hawsers by which we were secured and obliged me to let go a bower anchor; this falling on gravel did not bring the ship up until she had drifted half a cable's length outside the barrier of "floe-bergs" from which the pack was slowly retreating towards the north-east. The gale continued all night and drove the pack two miles off shore, but its constant motion to the eastward kept it tight in against Point Sheridan and cut us off from all chance of advancing. I was much struck at the time by the pertinacity with which the pack kept its ground during this severe gale, and could not help fearing that there would be little chance of its opening out sufficiently to allow us to advance much farther this year; but knowing well the occasional inexplicable uncertainty in its movements we still hoped for the best.

On the morning of September 2 the wind suddenly shifted from south-west to north-west, bringing the pack rapidly in towards the land, and causing the ship to swing broadside on to the heavy stranded ice; fortunately, the barometer having indicated the probability of a change occurring, steam had been kept ready, and after a considerable amount of manœuvring the anchor was weighed. Our protected dock was so small, and the entrance to it so narrow and encumbered with ice, that it was with extreme difficulty, much labour, and no trifling expense in broken hawsers, that the ship was hauled in stern foremost, with the united force of the wind and flood tide pressing at right angles to the course. It was a nice question whether the ice or the ship would be in first, and my anxiety was much relieved when, as the whole northern pack reached the outside of our friendly floe-bergs, I saw the ship's bow swing clear inside into safety, and the pack, instead of doing us an injury, considerably strengthen our protecting outwork by forcing new pieces on shore; at the same time, we could not help foreseeing that by so doing our chance of advancing when we wished was proportionately lessened. The danger we had so narrowly escaped from was forcibly represented to us all, as the pack, with irresistible force, swept past us to the eastward at the rate of a mile an hour, and constantly added to the accumulated masses outside.

The projecting point of a heavy floe would first ground in from ten to twelve fathoms of water; then the outer mass, continuing its course, unable to stop its progress, would tear itself away from its cast-off portion. The pressure, however, still continuing, the severed piece was forced, and frequently by the parent mass itself, up the steeply inclined shore, rising slowly and majestically out of the water 10 or 12 feet above its old line of flotation, and remaining usually nearly upright. The motion was entirely different to that produced when two ordinary floes some 4 or 6 feet thick met together; then, the broken edges of the two pieces of ice, each striving for the mastery, are readily upheaved and continually fall over with a noisy crash. Here, the enormous pressure, raising pieces, frequently 30,000 tons in weight, in comparative silence, displays itself with becoming solemnity and grandeur. What occurs when two 80-foot floes meet we cannot say; but the result, as far as a ship is concerned, floating as the ice does higher out of the water than herself, would be much the same as the closing together of the two sides of a dry dock on the confined vessel.

For the next three days we experienced light westerly winds; the ice remained close in to the coast, moving generally to the south-eastward, but occasionally stopping and closing up towards the north-west during the ebb tide. During the flood, pools of water, half a mile long by a quarter broad, frequently formed on the south-east side of the larger floes, but they were always completely isolated from each other by several miles of heavy ice. Although a few large floes could be distinguished in the offing, the pack within five miles of the land usually consisted of floes of less than a mile in diameter, with a very large proportion of rubble ice evidently broken off the large floes as they forced their way past the points of land to the north-west of us, the whole forming as rough a road for sledge travelling as could well be imagined.

At this period, although all regular navigation was evidently at an end, I was naturally most anxious to move the ship from her exposed position before the setting in of winter, but the quickly advancing season warned me that no movement should be made without a reasonable probability of attaining a sheltered position. Accordingly, Commander Albert Hastings Markham and Lieut. Pelham Aldrich started on September 5 to look at a bay seen from our hill station about eight miles distant from us to the westward. They reported that it was a well-sheltered harbour, thickly coated with this season's ice, but that the continuous wall formed by the grounded floe-bergs across the entrance to it would effectually prevent our entering.

After this report, with the temperature remaining steady between $+20^\circ$ and $+10^\circ$, and the barrier of grounded ice, which, although protecting, effectually imprisoned us, having increased in breadth to seaward for 200 yards, each heavy piece being compactly cemented in amongst its neighbours by the lighter broken up rubble ice, which was carried in by the tidal current, and frozen into position by the low temperature, I decided to commence landing such provisions and stores as were hampering the decks of the ship, and which would not be required during the winter, should we fortunately be able to move into safer quarters.

On September 6, 7, and 8, we experienced a heavy fall of snow, which, bearing down the young ice by its accumulated weight, allowed the water to percolate upwards, and render the floe very wet and unfavourable for travelling on. But not expecting any decided movement of the ice during the neap tides, and having secured the ship with a bower anchor and cable to the shore, and landed an ample depôt for the support of any travelling party in the event of accident to the ship, which at the time did not appear improbable, Lieut. Pelham Aldrich, accompanied by Capt. Feilden, R.A., and Dr. Edward L. Moss, started on a pioneering journey towards the north, and Lieut. Wyatt Rawson towards the south. The latter returned after two days' absence, having found the cape three miles from the ship, forming the entrance to Robeson Channel, impassable by land, on account of the steepness of the cliffs; and by sea, in consequence of the continual movement of the broken pack, which prevented him venturing on it, even with a boat. Lieut. Aldrich's party returned after an absence of four days. He had succeeded in establishing a depôt of provisions, and exploring the coast line for a distance of twenty miles to the north-west. The travelling was found to be unusually heavy, owing to the very rough state of the ice, and the deep snow, with its sticky wet foundation of sludge; indeed, so bad was it that although only laden with half weights, all three sledges broke down. The young ice in the few patches met with was too weak and treacherous to admit of heavy sledges journeying over it; one sledge broke through, and was only recovered with much difficulty.

On September 10 a westerly wind blowing off shore, force 4, combined with the ebb tide, opened for the first time since our arrival here, a narrow channel between the grounded ice and the pack extending for half a mile beyond Cape Sheridan, but trending out to seaward. On the 11th, the same wind continuing, the channel widened out until it was a mile broad, and extended for six miles to the westward, ending two miles distant from the shore. As this offered an opportunity of advancing a large depôt of travelling provisions and boats by water, Commander Markham started with a strong party, having first to launch the boats across the heavier barrier of ice within which the ship was sealed up, apparently frozen in for the season.

The sky being fairly clear, this was the first day on which we were able to pronounce decidedly concerning the northern land reported to exist by the *Polaris*. After a constant watch, and carefully noting the movement of the darkened patches, I was now with much reluctance forced to admit that no land existed to the northward for a very considerable distance. As seen through the light haze the dark reflection of the sky above the detached pools of water in the offing, in strong contrast by the side of the light reflected from the close ice, which in a great measure is similar to the bright glare reflected from a large sand flat, creates a very decided appearance of land when there is a mirage; indeed, sufficiently so as to deceive many of us when so anxiously expecting and hoping to see it. We, therefore, cease to wonder at the casual look-out men from the *Polaris* being mistaken, but the more experienced on board should not have allowed themselves to be so readily misled.

During the 13th and 14th the wind from the southwest gradually freshened, until on the latter day it was blowing a very strong gale, force 10 in the squalls, and evidently extending over the whole extent of Kennedy Channel; for the swell from the open water which it had produced on the weather shore extended round Cape Rawson, and reaching our position broke up all the light ice formed this season, and drove it out to sea, the large grounded floe-bergs alone remaining, with clear passages between them, through which we could have readily passed if requisite; but the main pack to the westward, although the channel leading to seaward had extended to between ten and twelve miles distance from us, still remained fast to the shore at a distance of about six miles from the ship.

The ship was secured by a bower cable, stern to the shore, one side resting against a large floe-berg, and bumping slightly against it with the swell. During the evening it was blowing furiously, with a blinding snowdrift, and whilst I was thinking of the uncomfortable state of the travellers in the tents in such a gale, I observed Commander Markham arrive abreast the ship. Although we were within 120 yards of the shore, it was only by double manning the oars of the cutter that during an opportune lull I was able to establish a hauling line between the ship and the shore, and so communicate with him; when it appeared that, having one man disabled from exhaustion, he had decided to push on for the ship to obtain assistance. With the help of the fresh men forming the cutter's crew, Capt. Markham and myself had the satisfaction of seeing the sledge party all on board before midnight, and the frozen man's life saved; but the sledge crew, who had so gallantly faced the storm, were all much exhausted, and in fact did not recover themselves for several days.

On the morning of the 15th the wind lulled considerably, and the remainder of Commander Markham's party, under the command of Lieut. Parr, returned, having passed anything but a pleasant time in their tents during the gale. On ascending our look-out hill I observed that the ice to the westward between the land and the channel in the pack had drifted to seaward, leaving a clear road by which we could advance to a place of shelter. Making a signal to the ship, steam was immediately got ready and the rudder shipped, but on lowering the screw we found it impossible to enter the shaft. Whilst raising it again to clear away the ice, a very thick snowstorm came on with a blinding mist, which, hiding everything from view, prevented our moving. Before midnight the storm was blowing as furiously as ever.

On the morning of the 16th, the gale still keeping the main pack clear of the shore, the weather cleared again, and another attempt was made to ship the screw, but without success, on account of the accumulated ice. While endeavouring to clear it the wind gradually shifted round to the north-west, and we had the mortification of seeing the pack rapidly nearing the land. By 2 P.M. it had reached the shore ice, and effectually closed us in for the winter. It never left the shore to the north-westward of our position afterwards, although a large space of clear water remained to the eastward between us and Robeson Channel, so long as the wind lasted from the eastward.

I may here add that on examining the coast-line afterwards, both during the autumn and the following spring, I am firmly persuaded that our forced detention during the late gale was most providential. There was no bay on the coast open enough to receive the ship, and the ice at the entrance of each was far too thick for us to cut or force our way through before the main pack had closed in.

Off the open coast where we were forced to pass our winter, the heavy nature of the ice constituted our safety; grounding in twelve fathoms, it was impossible that it could hurt the ship. At first I was rather anxious lest any lighter ice might be forced in, and that then the ship might be driven by it on shore, but as time advanced and nothing but ice of the same thick character made its appearance, I became more reconciled to our position. It ultimately proved to be the best sheltered position on the coast from which a ready means of retreat was likely to be offered. In all other parts, the beach, either by being too steep, allowed the heavy ice to force its way close up on to the shore, or where shallower, left a sufficiently large space of water in which smaller and more dangerous ice-blocks were able to drift about before they grounded in about the same depth of water as that in which the ship floated.

During the following week preparations were made for the autumn sledging, each man being fully employed fitting his travelling clothing and preparing the equipment of the sledges. As soon as the shore ice was sufficiently strong, Commander A. H. Markham, with Lieutenants A. A. C. Parr and W. H. May under his orders, started on September 25 with three sledges to establish a depôt of provisions as far in advance to the north-westward as possible. Lieut. P. Aldrich left four days previously with two lightly-equipped dog sledges to pioneer the road round Cape Joseph Henry for the larger party. He returned on board on October 5, after an absence of thirteen days, having been accompanied by Adam Ayles, A.B. On September 27, from the summit of a mountain 2,000 feet high, situated in lat. 82° 48′ N., somewhat further north than the most northern latitude attained by our gallant predecessor, Sir Edward Parry, in his celebrated boat journey towards the North Pole, he discovered land extending to the north-westward for a distance of sixty miles to lat. 83° 7′, with lofty mountains in the interior to the southward. No land was sighted to the northward.

On October 14, two days after the sun had left us for its long winter's absence, Commander Markham's party returned after a journey of nineteen days, having, with very severe labour, succeeded in placing a depôt of provisions in lat. 82° 44′ N., and in tracing the coast-line nearly two miles further north, thus reaching the exact latitude attained by Sir Edward Parry. Being anxious to inform Capt. Stephenson of our position, and the good prospects before his travelling parties in the following spring in exploring the north-west coast of Greenland, I despatched Lieut. Rawson again to attempt to open communication between the two vessels, although I had grave doubts of his succeeding. He was absent from October 2 to October 12, returning unsuccessful on the latter day, having found his road again stopped by unsafe ice within a distance of nine miles of the ship. The broken masses of pressed-up ice resting against the cliffs, in many places more than 30 feet high, and the accumulated deep snow-drifts in the valleys caused very laborious and slow travelling.

During these autumn sledging journeys, with the temperature ranging between 15° above and 22° below zero, the heavy labour, hardships, and discomforts inseparable from Arctic travelling, caused by the wet soft snow, weak ice, and water spaces, which obliged the sledges to be dragged over the hills, combined with constant strong winds and misty weather, were, if anything, much greater than those usually experienced. Out of the northern party of twenty-one men and three officers, no less than seven men and one officer returned to the ship badly frostbitten, three of these so severely as to render amputation necessary, the patients being confined to their beds for the greater part of the winter.

The sledges with their cargoes on four occasions broke through the ice, and individual men frequently; but these, becoming wet through, were made to change their clothing, and so escaped any bad consequences. The frost-bites are to be attributed entirely to the wet sludgy state of some of the ice that had to be crossed. It so happened that heavy snow fell on twelve consecutive days, forming a layer of lightly compressed snow at least 2 feet thick, which in the snow-drifts collected into ridges more than double that depth. The thin ice, not being sufficiently strong to support this additional weight, became borne down and allowed the water to ooze through. This being protected from the cold temperature of the air by its blanket-like covering, remained unfrozen, although the temperature was upwards of 40° below the freezing-point; consequently whenever the travellers, inexperienced as they were at the time, were forced to drag their sledges over a road of this nature, their feet became wet and afterwards frost-bitten a considerable time before they discovered it (when the tent was pitched in the evening), by which time the mischief had attained such an advanced stage as to defy all restoration of the circulation. The tent equipment became so saturated with frozen moisture that on arrival on board it weighed more than double what it did when dry before starting; and so anxious were all to escape another sleepless night in the stiffly frozen blanket bags, that on the last day a forced march was made by the northern party through the heavy snow to the ship, in which the powers of endurance of all engaged were tried to the utmost. All the travellers returned in wonderful spirits and full of pluck. Nothing could exceed the determined perseverance with which each obstacle to the advance of the party was overcome, or the cheerfulness with which each made light of the numerous unavoidable hardships they had undergone. The sledges proved to be too rigid; the uprights breaking necessitated frequent stoppages for repairs; but by taking out the metal pins connecting them to the upper bearers, and depending upon the hide lashings, they afterwards stood the unusually heavy work admirably.

On no one day while the northern party were travelling this season could they have obtained snow of sufficient consistency to enable them to build snow houses for shelter by night. Lieut. Rawson, finding harder snow in the southern ravines, was able to construct a snow house on one occasion. The advantageous results of the autumn travelling, in addition to the advance of provisions for future use, were, first, a considerable gain in experience in Arctic sledging, and secondly, by our greater good fortune in finding continuous land over or near which to travel, we succeeded in wresting from Sir Edward Parry and his companions their gallantly-achieved distinction of having advanced the British flag to the highes northern latitude. I have grouped the names of himsel and his followers together on the chart in the latitude t which they attained in 1827. On the return of the travelling parties, the sun having bidden us farewell, preparations were made for the winter; the ship was house over, all the provisions and stores which could withstan the weather, and for which room could not be found below hatches, were deposited on shore, and the habitable deck cleared as much as possible. By carefully covering ove the engine-room hatches with a thick layer of snow, th cold, throughout the winter, was kept from penetratin downwards into the lower part of the ship. The temperature of the holds and engine-room, without the use fires, always remaining above + 28·5, the temperature the surrounding water, and the fire-pumps which ha their suction pipes more than six feet below the water-line, remained serviceable to the last.

The long Arctic winter, with its unparalleled intensity and duration of darkness produced by an absence of sunlight for 142 days, was passed by each individual on board with much cheerfulness and contentment. Owing to the sameness in the daily routine, which, when looking into futurity, is thought to entail a long duration of dreary monotony, the time, in reality, passed with great rapidity, and in January, when the first glimmering increase in the midday twilight began to lengthen sensibly day by day, the want of light was scarcely noticed by any one; and not until the sun actually returned on March 1 did we in any way realise the intense darkness we must have experienced for so long a period. The manifold ordinary duties of the ship—to which were added the constant repair of the snow embankment, which, in consequence of our being frozen in close to a stranded piece of ice, was thrown down every spring tide—kept the ship's company fully employed, and gave them plenty of exercise during the day. On five evenings in the week a school, formed on the lower deck under Commander Markham and several of the officers, was well attended, each Thursday being devoted to lectures, songs in character, and readings, with occasional theatrical representations; the whole so admirably arranged and conducted by Commander Markham as to keep up the pleased interest of all for the whole period. The ventilation of the ship received the unceasing attention of Dr. Thomas Colan and myself, and owing to the large extra space amidships, left little or nothing to be desired in that respect. The health of the officers and crew, with only one exception, was most excellent, and the habitable deck as dry as is possible in these regions, in a ship without an extraordinary expenditure of coal.

With the arrival of the new year preparations for the spring travelling campaign commenced, the dogs being exercised daily under the superintendence of Mr. George Le Clere Egerton, Sub-Lieutenant, as soon as there was sufficient light. The pack in the offing remained in motion until the first week in November, when it gradually settled itself into position for the winter, the last pool of water being seen on the 16th of the month off Cape Rawson at the entrance to Robeson Channel. No movement, whatever occurred in the ice during the winter, except the formation of a tidal crack outside the grounded ice, which opened 2 or 3 feet during the spring tides. Although we had frequent evidence of strong winds prevailing in Robeson Channel, the weather at our winter quarters was remarkably calm; indeed we may be said to have wintered on the border of a Pacific Sea. The prevailing wind was from the westward; we never experienced any easterly winds; it always blew off the land. Had it not been for the intervening calms, the persistent westerly winds might have been well called a trade wind. On only two days were we prevented by the wind and accompanying snow-drift from taking exercise outside the ship. This quiet state of the atmosphere was productive of the severest cold ever experienced in the Arctic regions.

Early in March, during a long continuance of cold weather, the *Alert* registered a minimum of 73·7 below zero; the *Discovery*, at the same time, 70·5 below zero. In 1850 the *North Star*, at Wolsenholme Sound, in lat. 76° 30′ N., recorded 69·5 below zero. The *Alert's* minimum temperature for twenty-four hours was 70·31 below zero, the *Discovery's* minimum temperature for twenty-four hours was 67·0 below zero; Dr. Kane's, at Rensselaer Harbour, in lat. 78° 37′ N. in 1854, 58·01 below zero. Previously the longest continuance of cold weather recorded, that by Sir Edward Belcher at Northumberland Sound, in lat. 76° 52′ N., in 1853, was a mean temperature for ten consecutive days of 48·9 below zero. The *Discovery* experienced a mean temperature for seven consecutive days of 58·17 ditto. The *Alert* experienced a mean temperature for thirteen days of 58·9 ditto; and for five days and nine hours of 66·29. During February mercury remained frozen for fifteen consecutive days; a south-westerly gale, lasting four days, then brought warmer weather; immediately the wind fell cold weather returned, and the mercury remained frozen for a further period of fifteen days.

After the heavy snow-fall in the autumn previously alluded to, very little fell, and much trouble was experienced in obtaining sufficient for embanking the ship, it being necessary to drag some from the shore for that purpose. Owing to the small quantity which fell during the winter, estimated at from 6 to 8 inches, the summits of the coast hills were uncovered by the wind and remained so until May and the early part of June, when we again experienced a heavy snow-fall, estimated at a mean thickness of 1 foot. In the valleys and on the shores having an eastern aspect, the snow which fell remained light, and, unless snow-shoes were used, caused very heavy travelling. In the unprotected valleys and on the weather coasts the snow was sufficiently compact to afford fair travelling, much the same as that experienced in southern latitudes, where the more variable winds harden the snow everywhere.

Light flashes of aurora were occasionally seen on various bearings, but most commonly passing through the zenith. None were of sufficient brilliancy to call for notice. The phenomena may be said to have been insignificant in the extreme, and, as far as we could discover, were totally unconnected with any magnetic or electric disturbance.

During the winter Commander Albert H. Markham and Lieut. George A. Giffard employed themselves with much diligence and perseverance at the magnetic observatory, situated on shore, in a series of large and lofty snow houses, which were connected together with a covered snow gallery. Weekly observations were made with Barrow's dip circle for determining the inclination, and by means of Lloyd's needles for the total (relative) force. Occasionally these observations were repeated on the same day. The absolute horizontal intensity was obtained once every three weeks, and a series of hourly differential observations were obtained with the portable declination magnetometer on several consecutive days in the months of December, January, and February. At various places between Disco and the *Alert's* winter quarters, whenever opportunities offered, observations for inclination and total force were taken with Mr. Fox's instrument, observations for determining the absolute declination were also taken when opportunities occurred.

Lieut. Pelham Aldrich superintended the meteorological observations, also observations with Sir C. Wheatstone's polariscope, and Lieut. Alfred A. C. Parr, notwithstanding the severe season, obtained a good series of astronomical observations, also observations with the spectroscope and Sir William Thomson's portable electrometer.

I have not hitherto alluded to the services of Capt. Feilden, Paymaster, R.A., Naturalist to the Expedition, preferring that the report on the numerous scientific subjects to which he has directed his attention should emanate from himself; I will merely state here that not one moment has been lost by this indefatigable collector and observer. He has, moreover, by his genial disposition and ready help on all occasions, won the friendship of all, and I feel confident that their Lordships will highly appreciate his valuable services. I am only doing him justice when I state that he has been to this expedition what Sabine was to that under the command of Sir Edward Parry.

Dr. Edward Moss, a highly skilled and talented observer, in addition to his medical duties, kept himself fully employed in many branches of natural science; his investigations embraced studies of the floe-bergs and floes,

principally chlorine estimations, specific gravity estimations by Buchanan's method, and microscopy of dust strata; the chlorine and specific gravity estimations, and the microscopy of winter sea water; examination of air precipitates; estimation of carbonic acid and watery vapour in air; some experiments on the brittleness of iron at low temperatures.

The vicinity of our winter quarters proved to be unfavoured by game. On our first arrival a few ducks were seen and five shot, and during the winter and spring three hares were shot in the neighbourhood of the ship. This completes our list up to the end of May. In March, a wolf suddenly made his appearance, and the same day the tracks of three musk-oxen or reindeer were seen within two miles of the ship, but they had evidently only paid us a flying visit. In July six musk-oxen were shot, the only ones seen in our neighbourhood. The travelling parties were only slightly more fortunate in obtaining game. In June a few ptarmigan, ducks, and geese were shot and used by the sick. In July and August they obtained a ration of fresh meat daily. In March and the beginning of April about two dozen ptarmigan passed the ship, flying towards the north-west in pairs; finding no vegetation uncovered by snow in our neighbourhood, they flew on seeking better feeding grounds; they were nearly all shot subsequently by the outlying parties near Cape Joseph Henry. In the middle of May snow-buntings and knots arrived. A number of the young of the latter were killed in July, but no nests or eggs were found. Early in June ducks and geese passed in small flocks of about a dozen, flying towards the north-west, but owing to a heavy fall of snow, lasting three days, which covered the land more completely than at any other time during our stay, at east half the number returned to the southward, not pleased with their prospects so far north. Two dozen small trout were caught during the autumn and summer in lakes from which they could not possibly escape to the sea.

The total game list for the neighbourhood of the *Alert's* winter quarters, is as follows:—

	Musk-oxen.	Hares.	Geese.	King Ducks.	Eider Ducks	Long-tailed Ducks.	Ptarmigan.	Walrus.	Seals.	Foxes.

By Short Service Sledging Parties ...	—	13	3	5	—	—	10	—	—	—
Total	6	20	70	17	—	9	10	—	1	3

On March 1 the sun returned after its long absence.

The sledging season being now near at hand, I prepared orders for Capt. Stephenson to employ the whole force at his disposal in exploration of the neighbouring shore and the north coast of Greenland, instead of sending a party to communicate with Smith's Sound, as I considered that a sledge party employed on that duty this season would be performing unnecessary work, and that n the event of their Lordships communicating with Littleton Island, and finding that I had not visited it, hey would understand that the expedition was well placed or exploration far north, and that all was going on satisactorily.

March 4 was the day fixed for the dog-sledge to start to open communication with the *Discovery*, should the weather be favourable, but the severe cold which we then xperienced prevented their starting. The temperature emained unusually low until the 12th, when it rose to – 35°, and the weather being fine and settled, Mr. George Le Clere Egerton, Sub-Lieutenant, started in charge of the dog-sledge, accompanied by Lieut. Wyatt Rawson, belonging to the *Discovery*, whom I wished to consult with Capt. Stephenson concerning the exploration of the Greenland coast, and Christian Petersen, interpreter. As I knew that this journey was sure to entail very severe labour, Frederick, the Esquimaux dog-driver, not being a strong man, was left on board. Four days afterwards, the temperature having risen considerably in the interval, with a strong wind from the southward, the party returned in consequence of the severe illness of Petersen. He was taken ill on the second march with cramp in the stomach; and afterwards nothing could keep him warm. The tent being very cold, the two officers burrowed out a snow hut, and succeeded in raising the temperature inside to + 7°, but the patient still remained in an unsatisfactory condition, and it was only by depriving themselves of all their own warm clothing, and at the expense of the heat of their own bodies, that they succeeded, after great persistence, in restoring the circulation in his extremities to some extent. The following day, Petersen being no better, they wisely determined to return with him immediately to the ship. During this journey of sixteen miles, both Mr. Egerton and Lieut. Rawson behaved most heroically, and, although frequently very seriously frost-bitten themselves, succeeded in keeping life in the invalid until they arrived on board. He was badly frost-bitten in the feet, both of which had subsequently to be amputated. Notwithstanding the professional ability and incessant watchful care of Dr. Thomas Colan, he never recovered from the severe shock his system had received on this occasion, and eventually expired from exhaustion three months afterwards. He leaves a wife and family living in Copenhagen, who I trust will receive a pension.

On March 20, with fine weather and a temperature of 30° below zero, Mr. Egerton and Lieut. Rawson, having partially recovered from their most praiseworthy exertions when attending Petersen, again started for the *Discovery*, accompanied by two seamen, which they succeeded in reaching on the sixth day, after a very hard scramble over the rough ice in Robeson Channel, and along the steep snow slopes formed at the foot of the precipitous coast cliffs. No water was met with beyond that formed in the tidal crack, close to the shore. The temperature throughout the journey ranged from – 42° to – 24°. During the latter part of March the sledge crews were fully employed preparing their provisions, and equipping the sledges for the spring journeys. Long walks were taken for exercise, and a depôt of provisions was placed a few miles to the southward for the use of the Greenland division.

On April 3 the seven sledges and crews, numbering fifty-three officers and men, started on their journeys with as bright prospects before them as any former Arctic travellers—everyone in apparently the best possible health, and, while knowing the severe labour and hardships they would have to undergo, all cheerful, and determined to do their utmost. A finer body of picked men than the crews of the three extended sledge parties was never previously collected together.

Commander Albert H. Markham, seconded by Lieut. Alfred A. C. Parr, with two boats equipped for an absence of seventy days, was to force his way to the northward over the ice, starting off from the land near Cape Joseph Henry.

Three sledge crews, under the respective commands of Dr. Edward Moss, who in addition to his duties as Medical Officer to the division, volunteered to assume executive charge, and Mr. George White, Engineer, also a volunteer, accompanied them as far as their provisions would allow. Lieut. Pelham Aldrich, assisted by a sledge crew under the command of Lieut. George A. Giffard, was to explore the shores of Grant Land towards the north and west, along the coast line he had discovered in the previous autumn.

In regard to the first of these two journeys, that undertaken over the ice towards the north, it is my duty to its Commander and his followers to state that, knowing the extremely rough road over which they would be obliged to travel, I had little hope that they would reach a high latitude, for their daily progress with light or heavy sledges must necessarily be very slow. I thought it best, nevertheless, to make the experiment, to prove whether or not the Pole could be reached by a direct course over the ice without continuous land along which to travel. Having such willing and determined leaders as Commander Markham and Lieut. Parr, and the pick of the ship's company, who themselves were all chosen men out of numbers at hand, I sent them forth with full confidence that whatever was possible they would perform.

In organising this party, nothing was known of the movements of the Polar ice. I was even in doubt whether it was not always in motion in the offing, consequently I decided that boats must be carried of sufficient capacity for navigation, and not merely for ferrying purposes. This necessitated very heavy weights being dragged. It was also necessary that the party should carry a heavy load of provisions, for, owing to our clear weather and lofty look-out station, we had previously ascertained that no land existed within a distance of fifty miles of Cape Joseph Henry.

When a sledge party have to drag a boat even with only a few days' provisions, and over a smooth floe, double trips are necessary over the same road daily, in the same manner as Sir Edward Parry was compelled to journey in 1827, consequently, the utmost limit that could be transported in this way with two trips on level ice was chosen, and this provided the party for an absence from the land for sixty-three days. The plan usually resorted to of reducing the weights carried by the advance party by providing a chain of supporting sledges is not applicable when each assisting sledge requires a boat capable of carrying its crew.

On the day following the departure of our travelling parties, Mr. Egerton and Lieut. Rawson returned from the *Discovery* after a rough journey, with a temperature ranging between 44° and 15° below zero, but all in good health and spirits, and beyond sore noses and tips of fingers from frost-bites, were none the worse for their cold journey.

The news from the *Discovery* was most cheering with the exception that, although they had succeeded in obtaining upwards of thirty musk-oxen, one man was in the sick list with a bad attack of scurvy. With this exception the crew of the *Discovery* had passed a very comfortable winter, plenty of cheerful work leading to and inducing constant employment of mind and body, coupled with a fair share of mirthful relaxation and a frequent meal of fresh meat. I refer you, Sir, to Capt. Stephenson's full report for a detail of his proceedings. His crew were preparing for the exploration of Lady Franklin Sound and the coast of Greenland.

On April 8 the first supporting sledge returned from Commander Markham's and Lieut. Aldrich's parties. As usual on the first starting several of the travellers were much distressed by the severe and unaccustomed work, and the cold weather preventing sleep at night, but were gradually improving. One man who had been ailing slightly during the last month was sent back, and one of the crew of the supporting sledge returned with a frost-bite, the only serious case during the season, although the travellers, on two days out of the six that this party were away, experienced a temperature of − 46°.

On April 10 Lieut. Wyatt Rawson and Sub-Lieut. George Le Clere Egerton, having somewhat recovered after their cold journey to the *Discovery*, equipped with sledges, started to ascertain the nature of the ice in Robeson Channel, and to mark a convenient road across it for the heavier exploring sledges coming north from the *Discovery* under the command of Lieut. Lewis A. Beaumont.

On April 24 the second division of the supporting sledges returned, reporting the main parties to have settled steadily down to their work, and with the exception of one marine suffering from debility who was sent back, all were in good health and capital spirits. The temperature had fortunately risen to about − 26 degrees. The very cold weather had tried the party much, and there had been numerous light cases of frost-bites, which but for the presence and care of Dr. Moss might have proved serious. The appearance of the ice within six miles of the land was anything but cheering to the northern party, but they looked forward with hope that the floes would get larger and less broken up as they advanced. Each sledge carried extra tea in lieu of the usual midday allowance of spirits. Both men and officers were unanimous in favour of the change, and willingly put up with the misery of standing still in the cold with cold feet during the long halt needed for the purpose of boiling the water, and all agreed that they worked better after the tea lunch than during the forenoon.

On the 16th Lieut. Lewis A. Beaumont and Dr. Richard W. Coppinger arrived from the *Discovery*, having been ten days performing a travelling distance of seventy-six miles with light sledges, so broken up and difficult was the nature of the ice in Robeson Channel. They brought news that the ice was continuous and afforded fair travelling across Hall's Basin, and that the depôt of provisions at Polaris Bay was in good condition and fit for use. These circumstances enabled me to arrange for Lieut. Beaumont to proceed with lightly laden sledges along the Greenland coast to the eastward, and after completing his journey to fall back on the *Polaris* depôt before June 15, by which time two boats would be carried across the straits from the *Discovery*, ready for his retreat should the ice have broken up.

On the 18th Lieut. Rawson and Mr. Egerton returned, having succeeded in crossing the channel without finding more than the usual difficulties amongst the heavy hummocks, which they had now become so accustomed to. They had landed on the Greenland coast north of the position marked as Repulse Harbour, which proves to be only a slight indentation in the coast line, having a fresh-water lake inshore of it, which from an inland view might readily be mistaken for a harbour.

On April 20 Lieut. Beaumont, accompanied by Lieut. Rawson and Dr. Coppinger, started for his Greenland exploration, the few days' rest having materially benefited his men, who may be said to have started from the *Discovery* unexperienced in Arctic sledging, that ship having had no autumn travelling in consequence of the ice remaining in motion until a very late period of the season.

On April 23 Capt. Stephenson and Mr. Thomas Mitchell, assistant-paymaster in charge, arrived from the *Discovery*, and I had the advantage of consulting with the former unreservedly concerning the prospects of our numerous travellers then scattered over the neighbouring shores, the two ships remaining tenanted only by officers and a few invalids. Arrangements were made for the exploration of Petermann's Fiord, and should the season prove favourable, for the examination of the ice-cap south of Bessels Bay. On April 30 Capt. Stephenson returned to [illegible] *Discovery*.

Until the latter end of May sledge parties were continually arriving or departing, carrying forward depôts of provisions for the use of the distant parties on their return. In carrying out these duties I was much indebted to Dr. Edward L. Moss, who again volunteered to command a [illegible], and I the more readily availed myself of his services knowing that it would afford him a [illegible] continuing his scientific studies. Mr. James engineer, also assisted me materially as commander of a sledge party.

On May 3 Lieut. Giffard returned with news from Lieut. Pelham Aldrich up to April 25, his twenty-second day out from the ship. He reported that all his crew were well and cheerful, but that the soft snow was causing very heavy and slow travelling.

Up to this time all had gone well with the expedition. The two ships had advanced as far north as was possible; they were admirably placed for exploration and other purposes; and the sledge crews, formed of men in full health and strength, had obtained a fair start on their journeys under as favourable circumstances as possible. On May 3 Dr. Thomas Colan reported that five men had scorbutic symptoms; however, as each case had some predisposing cause, I was not alarmed until on the 8th the three ice quartermasters and two able seamen returning from sledge service were attacked, and by June 8 fourteen of the crew of the *Alert* and three men belonging to the *Discovery* who happened to be on board, forming the majority of the number of men then present, had been or were under the doctor's care for the same wasting disorder. Capt. Stephenson also reported that four more of his crew had been attacked.

Although many of the sledge crews formerly employed on Arctic research had been attacked by this disease some had totally escaped; therefore, considering the ample equipment and carefully prepared provisions with which the *Alert* and *Discovery* were provided, its outbreak was most inexplicable and unlooked-for. It was, however, most encouraging to learn from the report of former expeditions how transient the attacks had usually proved, and how readily the patients recovered with rest, the advance of summer, and a change to a more generous diet.

On May 9, by the return of Lieut. May and Mr. Egerton from Greenland, whither they had carried supplies and succeeded in discovering a practicable overland route immediately east of Cape Brevort fit for the use of the returning sledges should the ice break up, I received news of Lieut. Beaumont's party up to May 4, when he was within two miles of Cape Stanton. From their place of crossing the Straits they found that the coast line for nearly the entire distance to Cape Stanton was formed either by precipitous cliffs or very steep snow slopes, the bases of which receive the direct and unchecked pressure of the northern pack as it drifts from the north-westward and strikes against that part of the coast nearly at right angles. The floe-bergs, at their maximum sizes, were pressed high up one over the other against the steep shore; the chaos outside was something indescribable, and the travelling the worst that can possibly be imagined, seven days being occupied in moving forward only twenty miles. Being quite uncertain when such a road might become impassable by the ice breaking up in May as it did in 1872, a depot of provisions, sufficient for a return journey by land, was wisely left, but Lieut. Beaumont's journey was thus shortened considerably.

As nearly every south-westerly wind we experienced at Floeberg Beach changed its direction to north-west before it blew itself out, the coast of Greenland north of Cape Brevort must necessarily be a very wild one as regards ice-pressure, and a most uncertain coast for navigation. A vessel once caught in the pack-ice off that shore, if not crushed at once, runs a great risk of being carried by it to the eastward round the northern coast, as pointed out by Admiral Sir George Back, Kt., F.R.S.

During the first week in May the temperature rising to zero enabled me to remove the snow from over the skylights and bull's-eyes and let in light between decks, but owing to there being no skylight over the lower deck it still remained very dark. I would here remark, Sir, how very important it is that Arctic ships should, if possible, be fitted with a large skylight above the ship's company's living deck.

On May 24 Lieut. Giffard returned on board, after depositing Lieut. Pelham Aldrich's last depôt of provisions, he and his crew having performed their important work well and expeditiously; but I am sorry to add that he brought Dr. Colan two more invalids. The attack occurring on his outward journey, as it was of vital importance that he pushed on, Lieut. Giffard was necessarily obliged to leave them in a snow hut for five days, one man taking care of the other as best he could until the party returned. Lieut. Giffard acted with great judgment, decision, and consideration on this occasion, and the two invalids recovered before the ship broke out of winter quarters.

On June 1 Mr. Crawford Conybeare arrived with news from the *Discovery* up to May 22. Lieut. Archer had completed his examination of the opening in the land west of Lady Franklin Sound, proving it to be a deep fiord terminating in mountainous land, with glacier-covered valleys in the interior.

Lieut. Reginald B. Fulford, with the men returned from Lieut. Archer's party, then transported two boats across Hall's Basin to assist Lieut. Beaumont in his return later in the season. Capt. Stephenson, accompanied by Mr. Henry C. Hart, naturalist, overtook this party on the 12th at Polaris Bay. On the following day, the American flag being hoisted, a brass tablet prepared in England was erected at the foot of Capt. Hall's grave with due solemnity. It bore the following inscription:—

> "Sacred
> to the Memory of
> CAPTAIN C. F. HALL,
> of the U.S. Ship *Polaris*,
> who sacrificed his Life
> in the advancement of Science,
> on the 8th November, 1871.
> "This Tablet has been erected by the British Polar
> Expedition of 1875, who, following in his footsteps,
> have profited by his experience."

Dr. Coppinger, when returning from assisting Lieutenant Beaumont, had visited Capt. Hall's Cairn at Cape Brevort, and the boat depôt in Newman's Bay, and conveyed the few articles of any value to the *Discovery*. The boat itself, with the exception of one hole easily repairable, was in a serviceable condition. Capt. Stephenson returned to the *Discovery* on May 18, leaving Lieut. Fulford and Dr. Coppinger on the Greenland shore to explore Petermann Fiord. Mr. Crawford Conybeare having reported that the travelling along shore in Robeson Channel was fast becoming impracticable in consequence of the ice being in motion near the shore, his party were kept on board the *Alert*.

On the evening of June 8, Lieut. A. A. C. Parr arrived on board, most unexpectedly, with the distressing intelligence that nearly the whole of the crew belonging to the northern division of sledges were attacked with scurvy, and in want of immediate assistance. Commander Markham, and the few men who were able to keep on their feet, had succeeded in conveying the invalids to the neighbourhood of Cape Joseph Henry, thirty miles distant from the ship, but each day was rapidly adding to the intensity of the disease, and, while lessening the powers of those still able to work, adding to the number of the sick, and consequently, alarmingly increasing the weight which had to be dragged on the sledges. Under these circumstances, Lieut. Parr, with his usual brave determination, and knowing exactly his own powers, nobly volunteered to bring me the news, and so obtain relief for his companions. Starting with only an alpenstock, and a small allowance of provisions, he completed his long solitary walk, over a very rough icy road, deeply covered with newly fallen snow, within twenty-four hours.

Arrangements were immediately made to proceed to

Commander Markham's assistance; and with the help of the officers, who at once all volunteered to drag the sledges, I was able by midnight to proceed with two strong parties, Messrs. Egerton, Conybeare, Wootton, and White, the officers who could be best spared from the ship, taking their places at the drag ropes, Lieut. W. H. May and Dr. E. Moss pushing on ahead with the dog-sledge laden with appropriate medical stores.

By making a forced march the two latter, with James Self, A.B., reached Commander Markham's camp within fifty hours of the departure of Lieut. Parr, although they were, I deeply regret to state, unfortunately too late to save the life of George Porter, Gunner R.M.A., who only a few hours previously had expired and been buried in the floe. Their arrival had a most exhilarating effect on the stricken party, who were gallantly continuing their journey as best they could. Early on the following day the relief party joined them, when the hope and trust which had never deserted these determined men was quickened to the utmost, even the invalids losing the depression of spirits always induced by the insidious disease that had attacked them, and which in their case was much intensified by the recent loss of their comrade. Early on the morning of the 14th, owing to the skill and incessant attention of Dr. E. Moss and the assistance of the dog sledge conducted by Lieut. May and James Self, A.B., who, with a most praiseworthy disregard of their own rest, were constantly on the move, Commander Markham and I had the satisfaction of reaching the ship without further loss of life; and after a general expression of thanksgiving to God for his watchful care over the lives of the survivors, of placing them under the skilful charge of Dr. T. Colan, Fleet-Surgeon.

Of the original seventeen members composing the party, only five—the two officers and three of the men, John Radmore, chief carpenter's mate, Thomas Joliffe, first-class petty officer, and William Maskell, A.B.—were able to drag the sledges alongside. Three others, Edward Laurence, captain forecastle, George Winston, A.B., and Daniel Harley, captain foretop, manfully kept on their feet to the last, submitting to extreme pain and fatigue rather than, by riding on the sledge, increase the weight their enfeebled companions had to drag, and were just able to walk on board the ship without assistance. The remaining eight, after a long struggle, had been forced to succumb to the disease, and were carried on the sledges. Out of the whole number, the two officers alone escaped the attack of scurvy. After a few days' rest and attention, John Radmore, chief carpenter's mate, returned to his duty, and three of the others were able to attend on their sick comrades: but Thomas Joliffe, who had most manfully resisted the disease while actively employed, when his legs became cramped from resting on his return on board, was one of the most lingering cases. These men gradually recovered, and were all out of the sick list before the ship was free of the ice during the passage home.

In journeying to the northward, the route, after leaving the coast, seldom lay over smooth ice; the somewhat level floes or fields, although standing at a mean height of 6 feet above the neighbouring ice, were small, usually less than a mile across. Their surfaces were thickly studded over with rounded blue-topped ice humps, of a mean height above the general level of from 10 to 20 feet, lying sometimes in ranges, but more frequently separated at a distance of from 100 to 200 yards apart, the depressions between being filled with snow deeply scored into ridges by the wind, the whole composition being well comparable to a suddenly frozen oceanic sea. Separating these floes, as it were, by a broadened-out hedge, lay a vast collection of *débris* of the previous summers, broken up pack-ice, which had been re-frozen during the winter into one chaotic rugged mass of angular blocks of various heights up to 40 and 50 feet, and every possible shape, leaving little, if any, choice of a road over, through, or round about them. Among these was a continuous series of steep sided snow drifts sloping down from the highest altitude of the pressed-up ice until lost in the general level at a distance of about 100 yards. The prevailing wind during the previous winter having been from the westward, and the sledges' course being due north, these "sastrugi," instead of rendering the road smoother, as they frequently do in travelling along a coast line, when advantage can be taken of their long smooth tops, had to be encountered nearly at right angles. The whole formed the roughest line of way imaginable, without the slightest prospect of ever improving. The journey was consequently an incessant battle to overcome ever recurring obstacles, each hard-won success stimulating them for the next struggle. A passage had always to be cut through the squeezed-up ice with pickaxes, an extra one being carried for the purpose, and an incline picked out of the perpendicular side of the high floes or roadway built up, before the sledges, generally one at a time, could be brought on. Instead of advancing with a steady walk, the usual means of progression, more than half of each day, was expended by the whole party facing the sledge and pulling it forward a few feet at a time. Under these circumstances, the distance attained, short as it may be considered by some, was truly marvellous.

The excellent conduct of the crews and the spirit displayed by them, combined with the work performed, indicated in a striking manner the sense of confidence in the leaders which they enjoyed, and points unmistakably to the watchful care taken of themselves and to the general good guidance of the party.

No two officers could have conducted this arduous journey with greater ability or courage than Commander Albert H. Markham and his very able second in command, Lieut. A. C. Chase Parr, and I trust that their Lordships will notice their services by some mark of approval. The services of Thomas Rawlings and Edward Laurence, 1st class petty officers, filling the highly important positions of captains of the sledges, was beyond all praise. In addition to their general cheerfulness and good humour, to their care and skill must be attributed the safe return of the sledges, on which the lives of the party depended, uninjured, and in as serviceable a state as when they left the ship, notwithstanding the heavy nature of the road, which on all former occasions not only repulsed the travellers altogether, but drove them back with broken-up equipment. To such men as these, and the sledge crews generally, it is difficult to find any reward which can in the least compensate them for the manner in which they have manfully met the extreme privations and continuous labour necessarily undergone. During this memorable journey to penetrate towards the north over the heavy Polar oceanic ice, without the assistance of continuous land along which to travel, in which has been displayed in its highest state the pluck and courageous determination of the British seaman to steadily persevere, day after day, against apparently insurmountable difficulties, their spirits rising as the oppositions increased, Commander Markham and Lieut. Parr and their brave associates succeeded in advancing the National Flag to lat. 83° 20′ 26″ N., leaving a distance of 400 miles still to be travelled over before the North Pole is reached.

In order to attain this position, although a direct distance of only seventy-three miles from the ship was accomplished, the total distance travelled was 276 miles on the outward, and 245 miles on the homeward journey. Their severe labour and exertions which certainly can never be surpassed, coupled with the experience gained by Sir Edward Parry in the summer of 1827, proves that a lengthened journey over the Polar pack ice with a sledge party provided with a navigable boat is, in consequence of the rough nature of the road over which the party has to travel, impracticable at any season of the year; and further, as the sledges were necessarily advanced each stage singly, we are enabled to estimate the exact rate of progression which may be expected should anyone consider it desirable to push forward with light sledges without any additional means of returning later in the season in the event of the ice breaking up in his rear. The maximum rate of advance in this way was at the rate of 2¾ miles a day, the mean being at the rate of 1¼ miles a day.

It may be necessary here to state that the much to be deplored outbreak of scurvy, which certainly shortened the journey to the extent of some ten or twenty miles, in no way affects the conclusions to be derived from it. When the first two men who were attacked complained of sore legs, the disorder so commonly experienced by travellers in all countries, and particularly those employed to drag Arctic sledges, the loss of their services at the drag ropes was fully balanced by one of the two boats being left behind, thus, the daily distance accomplished during the first twenty-five days of the outward journey was not materially altered, and it was only during the latter fourteen days, that owing to the gradual breakdown of three more of the crew, the rate of advance was necessarily much retarded. The previous rate, however, had been so slow that the party gallantly continued their advance to the utmost limit of their provisions, confident that with the help of the manual labour of the officers, who from the first took their places at the drag ropes and pickaxes and worked as hard as the men, they could readily return to the land along the road on which they had expended so much labour in somewhat levelling during their outward journey.

The scurvy by this time having with very few exceptions, attacked the whole ship's company, I was somewhat anxious concerning the health of Lieut. Aldrich's men returning from their western journey; particularly when I observed that the cairn erected over his depôt of provisions, thirty miles to the north-west, remained untouched on the day appointed for his arrival there; accordingly I sent Lieut. May with the dog sledge, and three strong men to meet him. On June 20 the two parties joined company at the depôt and signalled their arrival to the ship. Lieut. Aldrich had crossed the land only just in time, for on the following day a gale of wind from the southward commenced bringing warmer weather, and the thaw set in with such rapidity that the snow valleys on the land were rendered impassable for sledges for the remainder of the season. Lieut. May met the party on the very last day, when most of them were able to travel, having succeeded in reaching, after a very severe journey most courageously borne, the same position to which Commander Markham's party had returned without assistance; but there the same blight that attacked the northern party, and against which the western division had long been struggling, gained on them so quickly that, with the exception of Lieut. Aldrich and Adam Ayles (P. O., 2nd class), the whole crew were placed *hors de combat*, James Doidge (1st class P.O.) and David Mitchell (A.B.) still gallantly struggling along by the side of the sledge, the other four invalids, having held out until the last moment, were obliged to be carried. Under these circumstances the arrival of Lieut. May with relief was most providential. With their assistance Lieut. Aldrich succeeded in reaching the *Alert* on the morning of the 26th, when, after again publicly returning thanks to Almighty God for his watchful care over the lives of the party, they were placed under Dr. Colan's charge, the officer being the only one not attacked by scurvy.

Notwithstanding a bad start, owing to the necessity of crossing the land with heavily laden sledges, Lieut. Aldrich with great energy succeeded in exploring the coast line to the westward for a distance of 220 miles from the position of the *Alert*. Trending first to the north-westward for ninety miles to Cape Columbia, the extreme northern cape in lat. 83° 7′ N., and long. 70° 30′ W., the coast extends to the west for sixty miles to long. 79° 0′ W. and then gradually trends round to the southward to lat. 82° 16′ N. and long. 85° 33′ W., the extreme position attained. No land or appearance of land was seen at any time to the northward or westward, and owing to the continued heavy nature of the ice, I conclude that no land can possibly exist within an attainable distance from this coast. Although most of the party suffered more or less during the outward journey, the attack was supposed to be merely transient, and it was not until they were returning home when the scorbutic symptoms of sore gums first made their appearance, that the real nature of the disease was in the least suspected. To these men equal praise is due as to their comrades employed in the northern division for the endurance and intrepidity with which each individual performed his respective duty. Crippled nearly as badly, they if possible suffered more severely; for being so distant from relief none could be carried without imperilling all, and each was obliged to remain toiling at the drag ropes making forced marches.

It is to Lieut. Aldrich's judicious care and energy during the long and anxious homeward march, seconded by the spirited example of Joseph Good, acting chief boatswain's mate, captain of the sledge, himself one of the most enfeebled of the party, that they owe their lives. Lieut. Aldrich's services on this, as on all other occasions during the three years he has been under my command, calls for my unqualified admiration; he is a talented and zealous officer, and in every way deserving of their Lordships' consideration.

Again, Sir, I have to bring to your notice the valuable services of Lieut. May and James Self, A.B.; the thaw having set in, it was principally due to their incessant labour that the party arrived on board before the rapidly advancing disease had further developed itself.

With regard to the outbreak of scurvy, which attacked the crew of the *Discovery* as well as ourselves, when the sledge crews started early in April, a finer body of men *in apparently perfect health it would have been difficult to pick anywhere, and I trusted that, owing to the excellent condition of our provisions, we were secure from any attack, but I must now conclude that disease was even* then lurking among us, and that the heavy labour of sledge travelling intensified and brought it out, as has been the case in nearly all former journeys when the travellers have been unable to procure large supplies of game, and were unprovided with lime juice. It attacked first the weakly men, afterwards the strong men who were predisposed for it, and most severely of all those who were employed on the longest and most trying journeys. Had there been no sledging work I believe that the disease would not have betrayed its presence amongst us, and had the officers been called upon *from the first* to perform as severe daily labour as their men I think that they would have been equally attacked.

On July 9, fifteen days after the return of the last sledge party, thirty-six of the crew of the ship had been, and twenty-four were, under treatment for scurvy. This large number of patients, most of them requiring constant and special attention, necessarily taxed to the utmost the services of Dr. Thomas Colan, Fleet Surgeon, and his able second, Dr. Ed. Moss, Surgeon. Nothing could exceed their indefatigable patience and care. The deprivation of necessary rest and exercise cheerfully submitted to by Dr. Colan, upon whom the chief responsibility fell, considerably impaired his own health, following as it did so closely on his long anxious watch by the bedside of Neil Petersen.

In order to preserve the continuity of the narrative, I will here report the result of Lieut. Beaumont's exploration on the Greenland coast, but which I only learnt some time afterwards.

On August 6, while the *Alert* was imprisoned by the ice twenty miles north of Discovery Harbour, during her passage down Robeson Channel, Lieut. Rawson and two men arrived with letters from Capt. Stephenson containing the distressing intelligence that scurvy had attacked the Greenland Division of sledges with as much severity as it had visited the travellers from the *Alert*, and that Lieut. Beaumont was then at Polaris Bay recruiting his men. I must refer you, Sir, to Capt Stephenson's letters and to Lieut. Lewis A. Beaumont's report for a full detail of the proceeding of this party, but I may here mention the chief points. I have already reported their movements up to May 5, when Dr. Coppinger left them; Lieut. Beaumont with two sledge crews journeying to the north-eastward along the north coast of Greenland, all apparently in good health. A very few days after, James J. Hand, A.B., who had passed the winter on board of the *Alert*, showed symptoms of scurvy. As soon as the nature of the disease was decided, Lieut. Beaumont determined to send Lieut. Rawson with three men and the invalid back to Polaris Bay, and to continue the exploration with reduced numbers. Lieut. Wyatt Rawson parted company on his return on May 11; but owing to two more of his crew breaking down, leaving only himself and one man strong enough to drag the sledge on which lay the principal sufferer, and to look after the other two, he only succeeded in reaching the depôt on June 3, James J. Hand unhappily dying from the extreme fatigue a few hours after the arrival of the party at Polaris Bay. Out of the other men forming the sledge crew, who had all passed the winter on board the *Alert*, only one of them—Elijah Rayner, Gunner, R.M.A.—escaped the insidious disease; George Bryant, 1st class petty officer and captain of the sledge, and Michael Regan, A.B., were both attacked, the former, although in a very bad state, manfully refused to the last to be carried on the sledge, knowing that his extra weight would endanger the lives of all.

I cannot praise Lieut Rawson's conduct on this occasion too highly; it is entirely due to his genial but firm command of his party, inspiriting as he did his crippled band, who relied with the utmost confidence on him, that they succeeded in reaching the depôt. His return being totally unexpected, no relief was thought of, nor, indeed, were there any men to send. On June 7 Lieut. Fulford and Dr. Coppinger, with Hans and the dog-sledge, returned to Polaris Bay depôt from the exploration of Petermann Fiord; and, with the help of some fresh seal meat and the professional skill and care of Dr. Coppinger, the malady was checked and the sick men gradually regained strength.

Lieut. Beaumont, continuing his journey on May 21, succeeded in reaching lat. 82° 18′ N., long. 50° 40′ W., discovered land, apparently an island, but, owing to the nature of the ice, probably a continuation of the Greenland coast, extending to lat. 82° 54′ N., long. 48° 33′ W. By this time two more of the crew showed symptoms of scurvy, and soon after the return journey was commenced the whole party were attacked, until at last Lieut. Beaumont, Alexander Gray, sergeant-quartermaster captain of the sledge, and Frank Jones, stoker, were alone able to drag, the other four men having to be carried forward on the sledge in detachments, which necessitated always double and most frequently treble journeys over the rough and disheartening icy road; nevertheless, the gallant band struggled manfully onwards, thankful if they made one mile a day, but never losing heart; but Lieut. Beaumont's anxiety being intense lest relief should arrive too late to save the lives of the worst cases. Not arriving at Polaris Bay on the day expected, Lieut. Wyatt Rawson and Dr. Richard W. Coppinger, with Hans and the dog-sledge, started on June 22 to look for them, the two parties providentially meeting in Newman's Bay, twenty miles from the depôt. The following day Frank Jones [illegible] three officers and Alexander Gray to drag the four invalids, the dogs carrying on the provisions and equipage. On the 27th Alexander Gray was obliged to give in, and the officers had to drag the sledge by themselves, Gray and Jones hobbling along as best they could. On the 28th, being within a day's march of the depôt with the dogs, the two worst cases were sent on in charge of Dr. Coppinger, and arrived at the end of the march, but I regret to state that Charles W. Paul, A.B., who joined the expedition from the *Valorous* at Disco, at the last moment, died shortly after their arrival. The remainder of the party, helped by Hans and the dogs, arrived at the depôt on July 1, and it being impossible to cross the strait and return to the *Discovery* before the invalids were recruited, at once settled themselves down for a month's stay, those able to get about shooting game for the sufferers with such success that they obtained a daily ration of fresh meat. It was entirely due, under Providence, to the timely assistance dispatched by Lieut. Rawson, who, as senior officer at Polaris Bay, when there was not time to cross Hall's Basin and inform Capt. Stephenson of his apprehensions, acted promptly on his own authority and went to the relief of Lieut. Beaumont's party, that more casualties did not occur.

After such details it is scarcely necessary for me to allude to the services of Lieut. Beaumont. The command of the Greenland sledges, entailing as it did the crossing and recrossing of Robeson Channel—which in 1872 remained in motion all the season—required even greater care and judgment than is always necessary in the leader of an Arctic sledge party. My confidence in Lieut Beaumont, as expressed in my original orders to him, was fully borne out by his careful conduct of the party throughout this trying and most harassing march. He is a most judicious, determined, and intelligent leader, and as such I bring his services to the notice of their Lordships.

Capt. Stephenson by personal inspection having satisfied himself that the resources of the Polaris depôt were sufficient and appropriate for the subsistence of the men detached to the Greenland shore, although naturally anxious at their non-arrival on board the *Discovery*, was not alarmed for their safety. On July 12 Lieut. Fulford, with two men and the dog-sledge, were dispatched across Hall's Basin to Discovery Bay, and arrived there on the third day, having found the ice in motion on the west side of the channel, and experiencing much difficulty in effecting a landing. On the receipt of the news Capt. Stephenson instantly started with a relief party, carrying medical comforts, and arrived at Polaris Bay on the 19th. On the following day the ice was in motion on both sides of the channel. On the 29th Capt. Stephenson, with Lieut. Rawson, Hans, and four able men, with two invalids who could walk, started with the dingy for Discovery Bay, and after a very wet journey they landed on the west shore on August 2, Lieut. Beaumont and Dr. Coppinger, with five strong men, being left for a few days longer in order to give the other two invalids further time to recruit. The whole party ultimately re-crossed the Strait, and arrived at Discovery Bay on August 14, having been absent from their ship 120 days, several of the party who had wintered on board of the *Alert* having been absent since August 26 the previous year.

Great praise is due to Dr. Richard W. Coppinger for his skilful treatment of the disease; living as he and the party did for from six to eight weeks in tents on an Arctic shore without extra resources or medicines, except at the last, it is much to his credit that on their arrival on board the *Discovery* all the patients were able to perform their ship duties. All speak in the highest terms of Hans the Esquimaux, who was untiring in his exertions with the dog-sledge, and in procuring game—it was owing to his patient skill in shooting seal that Dr. Coppinger was able to regulate the diet somewhat to his satisfaction. Lieut. Reginald B. Fulford, and Dr. Richard W. Coppinger cleared up all doubt about the nature of Petermann Fiord, having reached at a distance of nineteen miles from the entrance, the precipitous cliff of a glacier which stretched across the Fiord.

On considering the result of the spring sledging operations, I concluded that, owing to the absence of land trending to the northward and the Polar pack not being navigable, no ship could be carried north on either side of Smith's Sound beyond the position we had already attained; and also that from any maintainable position in Smith's Sound it was impossible to advance nearer the pole by sledges. The only object, therefore, to be gained by the Expedition remaining in the vicinity for another season, would be to extend the exploration of the shores of Grant Land to the south-westward, and Greenland to the north-east or eastward, but as with the whole resources of the expedition I could not hope to advance more than about fifty miles beyond the positions already attained on those coasts, and moreover, although the crew were rapidly recovering from the disease which had attacked them, they would certainly be unfit for employment on extended sledge parties next year, I decided that the Expedition should return to England as soon as the ice broke up and released the ship. It was with the very greatest regret I felt it my duty to give up the very interesting further examination of the northern coast of Greenland.

Although pools of water formed along the tidal crack in the ice early in June, the thaw did not regularly set in before the last week of the month. On July 1 water in the ravines commenced to run, after that date the thaw was very rapid both on shore and on the ice, but no decided motion took place before the 20th. On the 23rd, with a strong south-west wind, the pack was driven a mile away from the shore, but, as in the autumn, no navigable channel made to seaward or along the land to the westward of Cape Sheridan. On the 26th a record was left in a cairn erected on shore detailing the work performed by the expedition, and of my intention to proceed to the southward. On the 31st, after considerable labour to clear away a passage through the barrier of floe-bergs which had so well protected us during the winter, we succeeded during a strong south west wind, which drove the pack out to sea, in rounding Cape Rawson and entering Robeson Channel on our return voyage. After a ten miles run along shore, through a fairly open channel between the pack and the cliffy ice foot bordering the coast, we were stopped by a heavy floe one-and-a-half miles in diameter nipping against the land four miles north of Cape Union, and there being no other protection attainable, the ship was secured in a small indentation among a group of grounded floe-bergs lining the shore off a shallow part of the coast. The ice in the offing drifted north and south with the tides in a nearly compact mass, that near the shore alone being loose, but in no way navigable.

Early in the morning of August 1, the heavy floe which had stopped us the previous day commenced to move, and was soon travelling to the northward with the whole strength of the tide at the rate of one-and-a-half miles an hour, scraping along the ice foot as it advanced towards the ship in a rather alarming manner. Steam being fortunately ready we cast off, and succeeded in passing between it and the shore, as after a severe wrench against a projecting point close ahead of us, a channel was opened by its rebound, as it coach-wheeled round the north point of the floe, turned in towards the land close to the position which we had vacated a few moments before.

The difference between an ordinary floe and Polar Sea ice was here exemplified completely; the former composed of ice about 6 feet in thickness, on meeting with an obstruction is torn in pieces as it presses past it; the latter being some 80 or 100 feet thick, quietly lifts any impediment away out of its course, and takes no further notice of it. Such was the case on this occcasion: the Polar floe, which we only escaped by a few yards, on nipping against the heavy breastwork of isolated floe-bergs lining the coast, some of them 40 feet high and many thousand tons in weight, which had lately formed our protection from the smaller ice pieces, tilted them over one after another, and forced them higher up the land-slope, like a giant at play, without receiving the slightest harm itself, not a piece breaking away. It was most providential, that by its twisting round the *Alert* was enabled to escape out of the trap in which she was inclosed.

Steering onward, so close to the shore ice-cliff—from 20 to 40 feet high, and having ten to twenty fathoms water alongside it—that the quarter-boats touched on several occasions, we reached within two miles of Cape Union, but in consequence of the pack remaining close in at the cape, both during the flood and ebb tides, the ship was again brought to a stop. Fortunately we were able to secure her abreast of a large water-course, the stream of which had been powerful enough to undermine the ice-cliff to such an extent as to allow fifty yards of it to break away and float off to sea; this left just sufficient space in which to secure the ship alongside the beach in such a manner that in the event of a nip taking place she would merely be forced on the shore before the floe itself grounded. Here we were delayed for twenty-four hours with the boats from the exposed side lowered down and moored in-shore for safety.

At half flood, the south-running tide, a narrow lead of water formed round the cape; steam was got up immediately, but owing to delay in shipping the rudder consequent on the tide running towards the bow carrying it under the ship's bottom, the ice closed in again before I could get round; it also cut us off from our friendly little haven, and I was therefore obliged to secure the ship during the north-running tide in a slight indentation in the high cliffy ice-foot. Fortunately being within half-a-mile of Cape Union, the run of the ice, as it passed to the northward round the Cape, kept at about twenty yards from the land until after it had passed our position; only the lighter ice pieces scraping their way along the ship's side.

As we would be exposed to the whole pressure of the ice during the south-going tide, at 4 P.M., low water, it being calm and no prospect of a westerly wind to open a navigable passage, I cast off and bored a short distance into the pack with the purpose of allowing the ship to drift round the Cape with the flood or south-going tide. The ice carried her with it about a quarter of a mile distant from the land, with no navigable water in sight, the whole pack moving steadily together without nipping to any great extent. As we passed we noticed that the front of the ice-foot was perfectly smooth, and would afford no protection whatever if we were obliged to leave the pack. As the tide slackened we succeeded with great trouble in steaming out of the pack just as the ice commenced to set to the northward with great rapidity. As it remained slack for some twenty yards from the beach, we were able to proceed slowly to the southward, close to the ice-foot; the midship boats being turned in-board, but the quarter-boats which could not be protected, being in constant peril of a squeeze. The water channel widened considerably as we approached Lincoln Bay, and we crossed it without any trouble, and arrived within five miles of Cape Beechey before the tide turned, to run south again, when I secured the ship alongside a heavy polar floe-piece, with the hope of again drifting south; but finding that the lighter pieces of ice were drifting faster and gradually inclosing us, I was obliged to cast off, and with much trouble succeeded in reaching the north side of Cape Beechey, before the north running tide made at noon, August 3. After two hours waiting, there being plenty of water space to the northward, a channel opened and allowed us to get round the Cape. Here the cliffy ice-foot comes to an end with the precipitous land. South of the Cape the land slopes down to the shore line, and is fronted by a breast-work of broken off floe-bergs similar, but somewhat smaller, than those lining the shore of the Polar Sea; among these the ship was secured in three fathoms water within twenty yards of the shore, a mile south of the Cape, and considering our much more exposed position during the winter, I thought the ship secure.

During August 4 the weather was overcast with snow squalls from the south-west, with a low barometer but not much wind. As the ice had closed in and locked the ship up completely, the sportsmen visited the lakes where three musk-oxen had been shot the previous summer. A number of geese were found all unable to fly; the old ones moulting were nearly featherless, and the young ones not yet having grown theirs; consequently fifty-seven were captured, a very welcome supply for the invalids, of whom we had ten still remaining. The ice remaining close, and being only twenty miles from the *Discovery*, Mr. Egerton, with a seaman for a companion, was sent to her on August 5 with orders for her to prepare for sea. They had a rough and troublesome walk over the hills, but arrived the same evening.

During our detention in this position, the pack in the offing drifted up and down the strait with the tide, the wind having the effect of increasing the speed of the current, and the duration of its flow both towards the north and the south. Although the ice generally was of a considerably lighter character than that in the Polar Sea, or at the northern entrance of Robeson Channel, a number of heavy Polar floes passed us, driven to the southward by the northerly wind, and set into Lady Franklin Sound and Archer Fiord rather than down Kennedy Channel. In fact, that Sound may be considered as a pocket receiving all the heavy ice driven south through Robeson Channel, and retaining it until the prevailing westerly winds carry it to to the northward again, and clear out the Sound ready to be re-filled when the north wind returns. It is only during seasons when northerly winds prevail considerably over the westerly ones, that the heavy Polar ice is carried south in large quantities into Smith's Sound and Baffin's Bay.

On August 6 the wind increased considerably from the north until it blew a gale. During the height of the flood or south-going tide a succession of heavy floe pieces passed us drifting down the strait, toying with our barrier of outlying protections, and turning one large one completely topsy-turvy. It was firmly aground in twelve fathoms water on an off-lying shoal some 200 yards from the main line of the floe-bergs, and on this and the previous days had been of great service in keeping the line of the drifting pack at a safe distance from us; but on this occasion the point of a large floe which was drifting south close in shore brought the weight of the whole pack on the doomed mass. As it received the pressure the floe-berg was reared up in the air to its full height of at least 60 feet above water, and turning a complete somersault, fell over on its back with a tremendous splash, breaking into a number of pieces with a great commotion and raising a wave sufficiently to roll the ship considerably. Our protecting floe-berg carried away, the ice moved in, forcing the lighter floe-bergs one after the other, as they became exposed farther in-shore, and at last nipped the ship slightly. This evening Lieut. Rawson and two seamen arrived from the *Discovery* with news of the Greenland division of sledges. On the morning of August 7, with the wind blowing slightly off the land, the ice eased off shore, and cleared the nip round the ship, but did not allow me to move to a more sheltered position. In the afternoon, a temporary opening occurring, steam was raised and the rudder shipped, but owing to some of the ropes fouling, the latter was not ready before the ice closed in and imprisoned us again. During the night the wind increased considerably, and with the south running tide the ice was being carried past us at the rate of two miles an hour. Owing to several heavy pieces grounding outside our line of barrier ice, the inner edge of the pack was guided more towards our position, and at last two heavy pieces wedged themselves against the ship, the inner one grounding alongside the ship after forcing her very close to the shore, and nipping her to such an extent that the ship was raised bodily 3 feet. As the tide rose the lighter ice in-shore gradually forced its way under the ship's bottom and relieved the pressure somewhat; so that after four hours she was only raised about 6 inches above her usual draught of water.

As there was now no hope of releasing the ship, except by cutting down the heavy piece of ice which was aground outside us, all hands were set to work with pickaxes to lighten it. On August 10, after three days' work, the ice having been sufficiently reduced, floated at the top of high water, and released the ship; the main pack moving off shore at the same time, we advanced five miles, and on the following day, after much trouble, succeeded in joining company with the *Discovery*. Sending all my sick men to the *Discovery*, the *Alert* was secured at the entrance of the harbour ready to start for Polaris Bay to relieve Lieut. Beaumont immediately the ice permitted me to cross; but his arrival on August 14, as before stated, fortunately rendered this passage unnecessary. The *Discovery* having embarked her coals and provisions, both ships were now ready to continue their voyage to the southward, but although water was observed in Kennedy Channel, the whole of Lady Franklin Sound remained filled with the ice brought to the southward by the late northerly gale. While waiting, ready to start, each of the ships tailed on shore at nearly low water, but floated again without damage.

We were delayed here with calm weather and consequent little motion in the ice until August 20, when, a chance offering, we pushed our way through the pack, which, gradually opening as we advanced, led us into comparatively open water off Cape Lieber, where a strong south-westerly wind had been blowing for several days but had not been able to force its way across the ice in Hall's Basin. As we neared Cape Lawrence, the ice, which had been getting closer as we advanced south, became so close that we must either return north, run into the pack, or secure the ships to some of the grounded floe-bergs or icebergs. I chose the latter, and entering the bay immediately south of the cape, we followed the coast until we found ourselves in a large inner basin perfectly land-locked, and I made the ships fast with perfect confidence, although with the spring flood-tide the ice was floating sluggishly in and gradually filling up the bay. It happened, unfortunately, that at the very top of high-water a rather insignificant-looking piece of ice pressed against the ship, when the floe-berg in-shore of us, and against which the ship was resting, having floated with the spring tide, allowed itself to be pressed in-shore, and suddenly we found the ship aground forward with deep water under the stern. Before any means could be taken to release her from this position the tide had fallen 14 feet at low water, leaving the fore foot and keel bare as far aft as the fore channels, the ship lying over on her bilge at an angle of twenty-two degrees. As the tide rose, the ship was lightened, the cables hauled aft, and the anchors lowered on to suitable pieces of ice. One of these was then hauled astern to a proper position, when by blowing up the ice the anchor was laid out with great ease. At high water the ship was hauled off without having received any injury. On August 22 a south-west wind opened a passage again, of which immediate advantage was taken, and we proceeded to the southward as far as Cape Collinson with only the ordinary troubles in ice navigation, during thick snow-storms, misty weather, and strong head winds. Off the cape, owing to the *Alert* being obliged to back astern to escape a nip, the two ships fouled for a few moments, and the *Discovery* lost a boat's davit, but by smart and skilful management saved the boat. I may here add that such has been the skill displayed by the officers of the watches of the *Alert* and *Discovery*, although the two ships have frequently been necessarily within touching distance of each other, and of the ice-cliffs and bergs, this is the only accident of consequence which occurred during the voyage. The ice closing in ahead, the two ships were made fast inside some grounded icebergs in Joiner Bay, one mile north of Cape McClintock.

In Rawlings Bay, south of Cape Lawrence, icebergs are found for the first time on coming from the northward. All to the northward may be considered as floe bergs. Few even of the initiated can distinguish one from the other, so like are they; and certainly any stranger would be deceived, the floe-bergs being frequently larger than the icebergs. The ice-foot is also totally different, being formed by the pressure of lighter ice, it does not project into such deep water; consequently, whereas we could secure the ship alongside the ice-foot in Robeson Channel with confidence of her not grounding, in Kennedy Channel and all parts to the South of it there is only one fathom water alongside the icy cliff at low water.

Starting again in the evening, as an increasing south-west wind gradually opened the ice to the southward, we crossed Scoresby Bay, which, extending from fifteen to twenty miles in a south-west direction, was perfectly clear of ice, the fresh breeze blowing down it raising a sea which caused the ships to pitch slightly, and materially stopped their speed through the water. Approaching Cape Frazer, the wind was blowing a whole gale, and I was forced to expend much coal in reaching Maury Bay immediately north of it, and in which the two ships were anchored among a lot of grounded ice, but the squalls off the land rendered it anything but a safe or comfortable position. We were delayed three days rounding Cape Frazer and Cape Hayes, the turning point of the channel, and consequently a troublesome piece of navigation. On the 25th, after twice being driven back into Maury Bay, we succeeded in securing the ships inside some grounded icebergs near Cape Louis Napoleon, the same in all probability that sheltered us when bound to the northward the previous spring.

Much has been said concerning the expected difficulty of passing Cape Frazer, on account of the two flood tides, one coming south from the Polar Sea, and the other north from the Atlantic, being supposed to meet there, and by so doing collect a quantity of ice in the neighbourhood. Were ice navigation dependent on tidal currents alone, then at the position of slack water, where there is a minimum ebb and flow, a vast quantity of ice might be collected by the two flood tides, but on the other hand there would be an equal chance of the two tides carrying it away in opposite directions; however, as wind is of far greater importance than tidal movement, the case need not be considered. The two tides do meet at Cape Frazer, the actual position varying a few miles north or south according to the prevailing wind, and also the ice is certainly accumulated immediately about and south of the cape in great abundance. But this is owing to the ending of Kennedy Channel, and the strait widening considerably at that place into Smith's Sound proper. While many causes tend to keep narrow channels clear, enlarged seas with narrow outlets are naturally encumbered with ice.

I found no greater danger or trouble in passing Cape Frazer than in navigating elsewhere, except from what is caused by that cape being the turning point of the coast line, where no one wind blowing up or down the strait is able to clear away the ice on the north and south sides of the cape at the same time. Struggling slowly and patiently along, gaining about one mile a day by moving forward from the protection of one stranded iceberg to that of another, as slight movements in the ice during the calm weather allowed, and although obliged to enter the pack occasionally, always keeping as near the shore as prudent, we rounded Cape Louis Napoleon, and on the 29th arrived at Prince Imperial Island, in Dobbin Bay, everyone heartily thankful to be out of the pack, clear of the straggling icebergs, and for the ships to be secured to fixed ice once more.

During the previous week we had experienced much misty weather with a heavy fall of snow, measuring five inches, which changed the whole aspect of the land by reclothing the richly-tinted stratified mountains with their winter garb, from which they had only been free for a short seven weeks; afterwards the snow only melted slightly in the low-lying valleys. A northerly wind now set in, not strong enough to effect the movements of the ice materially, but sufficiently so to clear the atmosphere and lower the temperature considerably below freezing-point; after this date the young sea-ice formed continually day and night. As the mist cleared away it disclosed a fine panorama of lofty snow-clad mountains with glacier-filled valleys intervening; one large one extending to the shore discharges numerous icebergs into Dobbin Bay. This, the largest discharging glacier on the west shore of Smith Sound, was named after the Empress Eugenie, who, besides taking a personal interest in the expedition by her thoughtful present of a number of homely but most useful articles, added considerably to the comfort and amusement of each individual.

On September 1 we crossed Dobbin Bay and succeeded in securing the ships to an iceberg aground only a quarte of a mile from the depôt of provisions left by us the previous spring a few miles north of Cape Hawkes, but such was the thickness of the newly-formed ice that boat work was nearly out of the question; by working in the crack opened by the ebb tide some of the provisions were embarked, but there is still a boat and a large quantity o biscuit left on shore there. The same reason prevente my landing on Washington Irving Island and visitin our own cairn until the third day, when the spring tid having opened a water passage *I found that our notic had not been visited since we left it. The two old cairns erected by former travellers were again visited; the lichens* which had spread from stone to stone proving that they are *undoubtedly* of very ancient date. They were probably erected to mark the farthest north point reached by one of our enterprising and gallant predecessors who never returned home.

On September 3 a lane of water opening along shore to the westward of Cape Hawks, every exertion was made to reach it, but owing to the newly made ice, which by cementing together a number of loose pieces of old ice formed a barrier between us and the water, we only succeeded, after long perseverance, in ramming our way through it at a large expenditure of coal. After rounding the Cape, the pack by drifting away from the land had left unfrozen water and numerous detached small floes which forced us to make a very serpentine course, and occasionally to pass within thirty yards of the low ice foot on the shore, fortunately always finding deep water The outer pack, consisting of heavy ice, was closely cemented together by this year's frost; it contained fewer icebergs than we observed last year.

We succeeded in reaching Allman Bay, half-way between Cape Hawks and Franklin Pierce Bay, but here the water ended, and the new ice was so strong that I thought it better to wait for the chance of an opening instead of forcing our way through it with full steam. On the following day, no sign of an opening occurring, and wishing to get to a more sheltered position on the western side of the bay, the *Discovery* being better adapted for the work than the *Alert*, led the way under full steam forcing a canal through the ice, which was 1 to 3 inches thick. She was several times completely stopped, until with all hands running from side to side on the upper deck and rolling the ship, she cleared herself and obtained headway again. At the head of Allman Bay we found a long valley leading down from the lofty hills far back in the interior filled with a gigantic glacier, probably extending eastward nearly to Dobbin Bay. It was named after Mr. Evans, the President of the Geological Society In the Bay the temperature of the surface water was 32°, whereas since the frost had set in we had not met with any above 30. On testing it was found to be nearly fresh, which fully accounted for the increased thickness of the newly formed ice. We afterwards found the same phenomenon in the neighbourhood of each glacier stream that we passed, proving that the water under the glaciers being cut off from the increasing cold remains unfrozen, and running after the temperature of the air is considerably below freezing point.

The ice prevented our further movement until September 6. Early on the 7th, after one halt to allow the ice to open, we reached Norman Lockyer Island, with water channels for a third of the way across Princess Marie Bay. The season was now getting so late that one false step would probably entail our passing another winter in these seas without any adequate result being derived; therefore before attempting to cross the bay I walked to the summit of the island with Capt. Stephenson, and from there we had the cheering prospect of seeing a large space of open water some twenty miles distant from us which we knew would extend to the entrance of Smith's Sound, with only a few troublesome-looking nips between us and it. Making a signal to the ships we hurried on board, and with the exception of one nip which cost us an hour to clear away with all hands on the ice, and the *Discovery* charging at it repeatedly with full steam, we succeeded in getting two-thirds of the distance across the Bay; but there we were stopped by three extensive Paleocrystic floes which tozzled in between some grounded bergs, and Cape Victoria prevented the ice from drifting out of Princess Marie Bay The open water was now in sight from the mast-head, but the supply of coal was getting so low that if we did not succeed in releasing the ships the allowance for the second winter would have to be much reduced. On the 9th, as the ice moved at the change of tides, we advanced about a mile. On the morning of the 10th, observing that the heavy ice was likely to pass clear of the icebergs which imprisoned it, steam was got up ready, and five minutes after the channel was opened we passed through and found ourselves clear of Cape Victoria.

After this there was only one serious obstacle to our advance. Owing to the very calm weather the new ice had now frozen so strong that full steam was always necessary, particularly so wherever we had to force our way through ice where scattered pieces of old ice had been re-frozen closely together. At our last barrier of this kind, after the *Alert* had repeatedly charged the nip with full steam and considerable speed on, with no result, the *Discovery* ranged up alongside, and there being a narrow piece of heavy ice which would prevent the two ships actually touching, we made a charge together, and succeeded in forcing the barrier and gaining the open water beyond. From here the water channel permitted me to make a clear run for Cape Sabine, the ice opening as we advanced until none was in sight from the mast-head. On passing the entrance of Hayes Sound a considerable quantity of ice was observed some distance inside it.

In comparing the voyage of the *Polaris* and that of the *Alert* and *Discovery*, I believe that a vessel might have passed up the channel with equal fortune as the *Polaris* without encountering ice during the south-west gale we experienced in the middle of September, 1875. The heavy sea which on that occasion was produced in Robeson Channel indicated that there was a considerable stretch of clear water to the southward. The difficulty would be the choice of a starting point so late in the season after the frost has set in. If carefully navigated, a vessel, although kept ready to make a start, ought by that time to be secured in a sheltered position fit for winter quarters; and, therefore, would most probably be unable to reach the channel of open water when it formed. If incautious, she would be as helpless in the pack The best starting points are Port Foulke and Port Payer, at the entrance of Smith's Sound. The *Polaris*' quick passage north was entirely due to her leaving the entrance of Smith Sound at an opportune moment late in the season; had she left at any other time she would have experienced the same trouble in getting north in 1871 as in returning south the following year. There was as much in the channel in 1871 as in 1872—75—76. To the latitude of Polaris or Discovery Bay, if no accident happens to the ship, the passage may probably be made with perseverance most years by starting early in the season, but it will at all times be a most dangerous one.

In Robeson Channel the difficulties are greatly increased, and the passage may be said to depend as much on a fortunate combination of circumstances as on skilful navigation. The present expedition was 25 days in going and returning between Cape Sabine and Discovery Bay, the distance being 250 miles; 7 days in proceeding from Discovery Bay to the Arctic Sea, and 12 days in returning, the distance being 76 miles.

Sail was only used once on the passage north, the distance run being 20 miles, it was never used during the passage south. It is, therefore, totally out of the question a sailing vessel ever making the voyage; nevertheless, as full steam was only necessary on two occasions, a powerful steamer is not necessary. When the ice is decidedly closing no power at present available is of the slightest use; when it is opening, easy speed generally carries the ship along as fast as the ice clears away in advance of her; it is rarely that a quick dash forward is necessary.

In a very exceptional season a ship might be carried nearer towards Cape Joseph Henry than Floeberg Beach on the west shore, and probably into Newman Bay on the east shore of the entrance to Robeson Channel; but from the experiences we have gained I most confidently report that no vessel will ever round the promontory of Cape Joseph Henry, or pass beyond Cape Brevoort in navigable water.

Every observation indicates that the last few years have been mild at the settlements on the west coast of Greenland, and open seasons with regard to the ice in Baffin's Bay; little or none having been met with north of Cape York in July and August. The settlement at the Whale Fish Islands has been temporarily withdrawn, owing to the thin state of the ice rendering the fishing dangerous; and the temperature of the water as we proceeded south, through Baffin's Bay, was so high that navigation could scarcely be interrupted off Disco before the end of the year; indeed, the Inspector intended to be absent in an open boat in the month of November. With a maximum body of water the ice formed on it in one winter will be considerably lighter or thinner than it would be, had a quantity of ice been left floating about on its surface ready to be re-frozen thicker, and cemented with the new ice into one floe during the coming winter. Thus, one open season certainly leads to another; and unless fortuitous circumstances occur, such as continuous south-west gales, during the summer months, the season of 1877 must be a very open one in Baffin's Bay. North of Smith's Sound the season is probably entirely different to that of Baffin's Bay, for the same northerly winds that carry the ice to the southward towards Davis Straits, must fill up Smith's Sound with heavy Polar ice and produce a cold season. Southerly winds which keep the ice north in the Bay would as certainly clear out the channels to the northward, empty the ice into the Polar Sea, and produce a milder season than usual.

From Hayes Sound to Cape Beechey, in lat. 81° 52′ N., where Robeson Channel is only thirteen miles across, numerous Esquimaux remains stud the whole line of the west shore of Smith's Sound. To the southward of Cape Beechy the coast line affords fair travelling, to the northward the precipitous cliffs cut off all further advance, except during the depth of winter, when the ice in the channel is stationary. A very careful examination was made of the coast north of Cape Union, and I can report with confidence that Esquimaux have never had a permanent settlement on that shore. All the facts collected by our numerous observers lead me to conclude that the wanderers crossed Robeson Channel from Cape Beechey to Cape Lupton, where the *Polaris* Expedition discovered their traces.

The few pieces of drift wood, all of the fir or pine species, that have been obtained on the shores of the Polar Sea have evidently drifted to the position in which they were found from the westward. One piece was obtained lying on the surface of the sea ice itself, two miles distant from the land, the rest were found on the shore at different heights above the sea level up to 150 feet; the former was perfectly fresh with the bark on; the latter in all stages of decay, usually imbedded in the mud of dry ancient lakes evidently formed by the rising of the land, and of very great age. Besides these evidences of the rising of the land, the clearly defined smoothing of the [illegible] at all the prominent capes, from the present ice level up to 300 and 400 feet until the marks are lost in the gradually decomposing rocks, caused by the pressure of the bordering ice-foot and the grounding ice as it is forced against the land by the drifting pack, and the numerous sea-shell beds and mud deposits at high elevations were most noticeable.

At Floeberg Beach the salt-water ice formed during the winter attained its maximum thickness of 75½ inches early in June. In a fresh-water lake at the same date the ice was 79½ inches thick, with 12 feet depth of water at a temperature of 32° below it. This proves decidedly that the deep lakes do not freeze to the bottom during the winter. The lowest temperature registered by a thermometer buried 2 feet in the ground beyond the influence of any sudden variation was 13 degrees below zero; 59 degrees warmer than the air at the time. It rose gradually as the summer advanced, and at the end of July had risen to 29.5°. By that time the ravines had nearly stopped running, and the weather was becoming gradually colder. The sun's rays were most powerful on June 13 and 21, when a thermometer, with a blackened bulb in vacuo, registered + 128 and + 129 degrees, the temperature of the earth's surface at the time being + 27 and of the air + 34 degrees.

The coldest temperature of the sea-water during the winter was 28·25°, the same at all depths. On several occasions the Casella reversible thermometer showed that the temperature of the surface water, south of Robeson Channel, was colder than that of the underlying stratum, the difference amounting on one occasion to 1½ degrees Fahrenheit.

At Floeberg Beach the time of high water full and change, 10h. 44m.; spring rise, 3ft. 0in.; neap rise, 1ft. 7¾in.; neap range, 0ft. 5in.

As I had deposited a notice of our proceedings at Norman Lockyer Island and intended calling at Cape Isabella I ran past our station near Cape Sabine without visiting it; observing that the cairn was intact and appeared to be in the same state as we left it. Payer Harbour and the neighbourhood was clear of ice.

We arrived off Cape Isabella on September 9, the weather still remaining calm. On landing, a small mail of letters and newspapers which had been left by the *Pandora* was found at the dépôt, the dates informing us that the visit was made this year, but beyond a notice [illegible] that if possible a duplicate box of newspapers would be landed at Cape Sabine, we found no record of her previous or intended movements. Concluding that the remainder of our mail was left at Disco, and being short of coal, and the weather very calm, I pushed on towards the Carey Islands, without losing time by visiting Littleton Island on the opposite side of the strait. A southerly wind springing up, the ships were put under sail. Beating to the southward, we fetched into Whale Sound on the 11th without meeting any ice since leaving Smith's Sound. The wind having freshened into a gale I anchored in Bardin Bay on the evening of the 12th, where we observed some Esquimaux on shore, but the weather continuing very bad, I, unfortunately for them, put off communicating until the following day. On the same night the wind shifted suddenly and forced us to get under weigh, when the misty weather and a dark night prevented my landing at their settlement. The rock a-wash off Cape Powlet, the east point of the entrance on which the Esquimaux village stands, is very dangerous. There is no good anchorage obtainable outside of Tyndall Glacier; we were obliged to anchor in twenty-three fathoms in a position exposed to the northward, the *Discovery* making fast astern of the *Alert*.

During the 13th and 14th we worked to the southward towards Wolstenholm Island with calm and light airs from the west, which prevented my reaching the Carey Islands except at a large expenditure of our rapidly diminishing stock of coal; the heavy swell left from the late southerly gale would also have prevented our landing; accordingly our letters, left there the previous year by the *Pandora*, were obliged to be sacrificed.

From Wolstenholm Sound a south-easterly wind enabled us to fetch across to Cape Byam Martin at the entrance of Lancaster Sound, where we arrived on the 16th, having seen no field ice, and the temperature of the sea-water ranging from 31 to 34 degrees. Steaming to the eastward on the 18th, we met another south-east wind, which carried us into the south part of Melville Bay, and we proceeded south along the Greenland shore. I preferred recrossing Baffin's Bay rather than by standing to the southward risk getting in-shore of the middle ice on the west side. On the 20th Cape Shackleton was sighted, and on the 25th we arrived at Disco, having had persistent head winds since we left the entrance of Smith's Sound on the 10th. Only one light stream of ice was fallen in with all this part of the voyage. Here Mr. Krarup Smith, Inspector of North Greenland, most considerately allowed us to take 30 tons of coal out of his small store, and informed me that there were 20 tons more at my disposal if I would visit Egedesminde; and in order to give the Expedition the full benefit of his presence in obtaining supplies, Mr. Krarup Smith accompanied the ship to that port. Nothing could exceed his kindness to us during our stay. Finding that several of the inhabitants of Egedesminde were attacked with scurvy, I made the Governor a present of lime-juice for general use. From Mr. Smith we learnt that all our letters, with the exception of the few left at Cape Isabella, had been deposited at Littleton Island. Only a few letters were received at Cape Isabella; therefore a large mail of private and official correspondence has been lost.

After coaling and preparing the ships for sea we left Egedesminde on October 2. On October 4 the two ships recrossed the Arctic Circle, exactly fifteen months from the time of crossing it on the outward voyage. Experiencing contrary winds, slow progress was made to the southward. As the weather became warmer and damper a few men were attacked with rheumatism and colds. On the 12th, during a very severe gale, in which the ships were hove to under a close-reefed main topsail and storm staysail, the *Alert's* rudder head, sprung when the ship was in the ice, worked adrift from the irons with which it had been repaired, the lower part of the rudder being sound. As I had neglected to have the rudder pendants shackled on before leaving port, it was with no little difficulty that make-shift rudder pendants were improvised; but by their means the ship has been steered across the Atlantic, the sails being trimmed to bring as little strain as possible on the rudder. The *Discovery* was lost sight of during a heavy gale on the 19th. During the passage, southerly winds prevailed. The spare rudder, itself badly sprung, has been repaired, and is in serviceable condition; when it is shifted the *Alert* will be ready to proceed to Portsmouth. Captain Stephenson, before parting company, was ordered to rendezvous at Queenstown.

In conclusion, it is my pleasing duty to inform you for the information of their Lordships, that one and all under my command have done their duty well and nobly, the utmost cordiality prevailing throughout the members of the Expedition from first to last. Capt. Stephenson has been a most valuable colleague, and I am much indebted to him for his friendly advice, and ready help on all occasions.

The executive officers have each been mentioned in the detailed reports of Capt. Stephenson and myself; their conduct when taxed to the utmost, under difficult and most distressing circumstances, is beyond all praise. Much as the attack of scurvy which visited us is to be regretted, it proved how valuable were the services of Fleet-Surgeon Thomas Colan, M.D., and Staff-Surgeon Belgrave Ninnis, M.D., who were so ably assisted by Surgeons Edward Lawton Moss, M.D., and Richard William Coppinger, M.D. These officers are each of great talent and high character, and have fully borne out the confidence imposed in them by the Medical Director-General; any reward that it is in the power of their Lordships to bestow on these gentlemen could not be given to more careful or zealous officers.

Lieuts. Lewis Anthony Beaumont and William Henry May, who voluntarily undertook the navigating duties in their respective ships, have performed that work most ably.

Lieuts. May and Robert Hugh Archer have charted the coast line from the entrance of Smith's Sound to the northward with great exactness; these officers have earned their Lordships' commendation.

The Expedition is much indebted to Mr. Thomas Mitchell, Assistant Paymaster-in-charge; the departure of the Assistant Paymaster of the *Alert* has much increased his work, as the only officer of his rank in the Expedition. In order the more readily to assist me, he performed a sledge journey in the early season from the *Discovery* to the *Alert*, and has since then divided his time between the two ships. He is a steady and trustworthy officer, and as such I recommend him for promotion. Mr. Mitchell and Mr. George White, Engineer, have made a most valuable collection of photographs of subjects connected with Arctic life and scenes.

The Engineers of the two ships have always most zealously assisted, like everyone else, in the general work, and fully occupied their spare time for the benefit of the Expedition.

Messrs. James Wootton and Daniel Cartmel deserve great praise for the invariable excellent order in which the engines under their charge have been kept, and for the careful economy of the coal supply, a vital point in Arctic exploration. Messrs. George White and Matthew Richard Miller are each careful and talented officers. I most confidently recommend the claims of these four gentlemen, who were voluntarily employed with the support sledges, to the favourable consideration of their Lordships.

The two ships' companies have conducted themselves in the most praiseworthy manner throughout; they are specially commendable for their resolute perseverance during the trying sledge journeys which have been already reported. Their good conduct and zeal entitles them to the most favourable consideration of their Lordships. A list of men specially deserving of and fit for advancement to higher rates will shortly be forwarded.

OUR ASTRONOMICAL COLUMN

THE NOVEMBER METEORS.—The earth will arrive at the descending node of the first comet of 1866 (Tempel), in the track of which the meteors of the November period are found to travel, early on the evening of the 13th inst. The comet itself is approaching the point of nearest approximation to the orbit of Uranus, which planet, however, is always far removed from the comet during the present revolution. The distance from the earth on November 13 is 19·06, and from the sun 18·11, the mean distance of the earth from the sun being taken as unity; and were we able to reach the comet with our telescopes it would then be found rather more than one degree to the west of Antares. The obvious existence of more than one point of excessive condensation in this stream of meteors, necessitates a strict watch at each return of the earth to the nodal point, if we are to arrive at a clear knowledge of the law of distribution along the orbit, and as was remarked by M. Leverrier, "cela permettra de comprendre ces questions dans une théorie plus précise."

HERSCHEL'S FIRST GLIMPSE OF URANUS.—Herschel's first observation for position of this planet on the night of discovery, March 13, 1781, was made at 10h. 30m. M.T. at Bath, when he found it 2′ 48″ distant from a star which he calls α. For those who are curious in such matters it may be stated that the tabular place of Uranus at this time is in right ascension 5h. 35m. 48·2s., and north polar distance 66° 27′ 3″, whence it appears that Herschel's first comparison was made with the star Argelander Z. + 24°, No. 1067, estimated 9·5m.; the difference of one minute of arc, between the observed distance and that computed on reducing the star to March, 1781, being probably due to error of position in the "Durchmusterung." The log-distance of Uranus from the earth was 1·2774.

THE TRANSIT OF VENUS, 1882.—Prof. Bruhns has circulated the results of a new calculation of the circumstances of this transit, made from Leverrier's tables of sun and planet, on the method adopted by Hansen for the transit of 1874. These results, allowing for small differences in the semi-diameters employed, are quite in accordance with those previously published by Hind, Puiseux, &c. Prof. Bruhns hopes to issue a chart of the limiting curves in this transit, founded upon this new computation, before the end of the present year.

MR. KNOBEL'S CATALOGUE OF THE LITERATURE OF SIDEREAL ASTRONOMY.—One of those exceedingly useful, but monotonous and laborious performances which exhibit the real zeal of the worker, occupies a large portion of the supplementary number of the "Monthly Notices" of the Royal Astronomical Society. It consists of a list of references to books, papers, &c., bearing upon the following subjects connected with stellar astronomy:—1. Double Stars, and the investigation of the orbits of Binary Systems; 2. Variable Stars; 3. Red Stars; 4. Nebulæ and Clusters; 5. Proper Motions; 6. Parallaxes of Stars; 7. Stellar Spectra; and, in the formation of this list, Mr. E. B. Knobel has had the advantage of the valuable library of the Royal Society, which is known to be remarkably rich in scientific transactions, &c., in addition to the library of the Royal Astronomical Society, to which numerous and important additions have been made of late years. In such a work it might not perhaps be difficult for any one who has interested himself in a particular branch of sidereal astronomy to suggest some addition which he would like to have seen incorporated. For instance, if a calculator of double-star orbits be looking up measures o α Centauri, he will find no reference to the valuable measures by Mr. E. B. Powell, at Madras, under his name.

Mr. Knobel's statement that with one exception he has "personally examined every paper or book to which reference is made," will afford an idea of the expenditure of time and trouble involved in the production of his catalogue. By the way, the one exception refers to the "Sidereal Messenger," issued by the late Prof. O. M. Mitchell, while director of the Observatory at Cincinnati, which Mr. Knobel says is "not in the British Museum nor the libraries of the Royal Society and the Royal Astronomical Society." The writer is able to testify to a circumstance from his own experience, which may throw some light on the rarity of this periodical in our scientific libraries. He was one of a favoured few in this country to whom Prof. Mitchell sent the "Sidereal Messenger." It arrived through the post in one or more numbers at a time, but the postal arrangements with the United States not being then on the liberal footing of the present day, and Prof. Mitchell unluckily enveloping his journal in a stiff cover, heavy letter-postage was demanded for the successive deliveries. The demand increased on each occasion, until the presentation of one, which would have left but small change out of a sovereign, closed the writer's knowledge of the "Sidereal Messenger," and he has some recollection that the present Plumian Professor of Astronomy informed him at the time that his own receipt of the paper terminated about the same epoch, and for a similar reason. If this be a mistake, perhaps the periodical to its termination may be found in the library of the Cambridge Observatory. No. 4 contains the author's early measures of the companion of Antares, which he detected at Cincinnati, in 1845, with measures of η Coronæ and one or two other double stars of no particular interest. The "Sidereal Messenger" was not continued for any length of time.

METEOROLOGICAL NOTES

CLIMATE OF MANITOBA.—In the *Journal* of the Austrian Meteorological Society for October 1, there appears a valuable paper on this subject by Dr. A. Wojeikoff, based on observations made for a period of about five years at Winnipeg, the capital of this province of Canada. The results, a monthly *résumé* of which accompanies the paper, show a mean atmospheric pressure about three-tenths of an inch less in summer than in winter, and in consequence of the position of Manitoba with reference to the diminished pressure in the interior of the continent at this season, N. and N.W. winds prevail there 19 per cent. less, and N.E. E., S., and W. winds 26 per cent. more in summer than in winter. Leaving out September, the rainfall of which appears to be exceptional, May and June are the two rainiest months, and next to these come April and July, the rainfall of Winnipeg being in these respects closely analogous to that of the prairie region of the Western States. The rainfall for the year is only 22 inches. The greatest amount of cloud and the greatest relative humidity occur in November. The mean annual temperature is 34°·0, the coldest month January, being 0°·5, and the warmest July, 66°·7. The winter temperature is thus as cold as that of Archangel, but the summer temperature as warm as that of Paris. The high summer temperature and generous rainfall from April to July, the rainfall rising from 1·85 inches in April to 3·58 inches in June, mark the climate of Manitoba as admirably suited for the successful cultivation of wheat, barley, potatoes, turnips and other agricultural products of temperate regions. Dr. Wojeikoff draws an interesting comparison between the climates of the prairies of Manitoba and Minnesota on the one hand, and the Steppes of Western Siberia on the other, and shows that the seasonal distribution of temperature of Winnipeg is all but identical with that of Ischim, and that of St. Paul with Saratow. An important climatic difference must, however, be kept in view, viz., the summer rains are several weeks earlier in Manitoba than in Siberia.

SIROCCO AT PAU.—In the same number M. Piche, Secretary of the Meteorological Commission of the Lower Pyrenees, communicates a short notice of a sirocco which occurred in that part of France on September 1, 1874, during which the temperature rose at Biaritz to 101°·3, and the humidity fell to 38, the humidity falling still lower, or to 33, at Eaux-Bonnes. The extraordinary heat and dryness of the sirocco, which came from the south and south-east are attributed by M. Piche to the course it had pursued, that course being from Africa, across the Pyrenees, and thence down on Pau, this wind being thus quite analogous to the föhn of the Alps. The sirocco of the Lower Pyrenees being merely the in-draught towards a low atmospheric pressure accompanying a great storm which is advancing from the west, it follows that as soon as the wind veers to W. or to N.W., and consequently no longer crosses the Pyrenees before reaching Pau, it may be expected that the air will become instantly saturated with moisture, and rain begin to fall. This is just what takes place, and the connection between the sirocco and Atlantic storms is well recognised, and finds expression in the weather-prognostic current at Pau, "The drier the air the nearer the rain."

THE NORWEGIAN ATLANTIC EXPEDITION.—Prof. Mohn communicates to the *Bulletin International* an interesting note on the Norwegian scientific cruise of last summer. The hourly meteorological observations will not only be discussed with a view to ascertain the diurnal periods during the summer months, but also be compared with simultaneous observations made on land with the view of tracing the connection which subsists between the weather and its changes on sea and land respectively In addition to the observations usually made on board the navy of Norway, the humidity of the air, the evaporation from sea-water, the velocity of the wind, and the rainfall were observed. The zoological collection is rich and varied, many of the species found are new to science, and will necessitate the establishment of new genera. A valuable collection has been made of specimens of the sea-bottom taken at each sounding, of sea-water from the bottom and the surface, and of the rocks and minerals of Farö and Westmanna Island. The stormy character of the weather prevented magnetic observations being made on board, but such observations were very carefully made at Husö, in Sognefiord, Reykjavik, and Namsos in Norway. The expense of the cruise, inclusive of the instruments and apparatus, has been 165,000 francs—an expenditure which can only be regarded as liberal for such a country as Norway—and it is intimated to be the intention of the Norwegian Government to resume the prosecution of the researches in the next two years, extending them in the direction of Jan Magen and Spitzbergen.

BAROMETERS OF SOUTHERN RUSSIA.—M. Moritz, the eminent director of the Tiflis Observatory, makes an important communication to the *Bulletin International* of October 26, regarding the barometers of the stations in the south of Prussia. Prof. Wild, in the *Annals* of the Central Physical Observatory of St. Petersburg for 1874, states that the barometer at Tiflis is 0·028 inch lower than that at Nicolaieff. The determination of the true difference of the readings of these two barometers is of more importance than appears at first sight, because the barometers of all the Russian stations on the borders of the Black Sea have their errors determined by that of the barometer at Nicolaieff, or as it is technically phrased, are controlled by it, whereas all the barometers of the Caucasian Stations are controlled by that of Tiflis. Now these southern Russian Stations, taken as a whole, can supply data, unique of its kind, towards the solution of such questions of general meteorology as concerns the influence of large sheets of water and lofty mountain ranges on the state of the atmosphere and its movements, if only we be quite certain that the barometric readings at the numerous stations over the region are comparable with each other. During the past summer M. Moritz has made a careful comparison of the Tiflis and Nicolaieff barometers, by means of two barometers which he carried from Tiflis to Nicolaieff, and back again to Tiflis, with the result that the difference between the two barometers by which so many barometers are controlled, is only a tenth part of the difference as given by Prof. Wild, or the difference instead of being 0·028 inch, is only 0·003 inch. The comparison of station barometers is a laborious and delicate operation. If the instrument be a Board of Trade barometer, having an air-trap, any air lodged in it renders the comparison worthless; if not furnished with an air-trap, any air admitted into the tube vitiates the comparison; and if care be not taken in hanging the barometers or in timing the observations so as to secure that each attached thermometer truly gives the temperature of the whole instrument with its contained mercury, the comparison is not satisfactory.

THE FALL OF TEMPERATURE IN END OF OCTOBER.—The weather maps of Europe of October 27 and following days show remarkable changes in the distribution of the atmospheric pressure and changes of temperature consequent thereon. On the 27th pressures were much higher in the east than in the west of the continent, accompanied with south winds and temperatures considerably above the average of the season in Great Britain; in other words the meteorological conditions were analogous to those described in a recent number of NATURE (vol. xiv. p. 536), as characterising the warm weather from October 4 to 7. On the 28th, however, barometers began to fall in the extreme north of Norway. This depression and a general lowering of the barometer was propagated southwards over Eastern Europe, while at the same time barometers rose to a considerable height over Western Europe. The necessary result, as regards the British Islands, of this altered distribution of pressure was a change of wind from south to north and a fall of temperature from about 5° above the average on October 27 and 28, to about 5° below it on October 31 and November 1. In addition to the interest of this illustration from its bearing on the importance of a knowledge of the weather in the extreme north of Europe in connection with weather forecasts for Great Britain, it is also interesting as a type of those meteorological conditions to which some of our severe winter weather is due. Indeed, some of our severest winter storms of wind and snow have occurred with barometric depressions which have advanced from the Arctic Sea southwards over Europe; and they are peculiarly severe in these islands when the centre of the depression takes a course more to westward than that of last week, or when it passes to the south-eastward over the North Sea or over Denmark.

NOTES

WE publish this week the complete Report of Capt. Nares on the Arctic Expedition, along with a new map showing in detail the various geographical discoveries made by the expedition, our map of last week being necessarily very general. We congratulate the Admiralty on the rapidity of the publication, and are glad to be able thus to place on permanent record the general report of the Commander of the expedition, both as to its work and its results. As we said last week, these results will be fully appreciated only when the various scientific reports are published. Of course various schemes have been proposed to accomplish the minor object in attempting to attain which our fearless men were baffled—the attainment of the Pole. A correspondent writes to us suggesting the use of a balloon to be inflated at the coal-bed in Discovery Bay, and crossing right over the Pole, about 1,000 miles, obtain a bird's-eye view of what is below. A correspondent in one of the daily papers advocates the use of steam, and that something like a tramway should be made to the Pole, the floe-bergs being tunnelled if necessary. Another of our correspondents endeavours to show that the ice-masses met with must have been pushed over from the Siberian coast, though this seems somewhat inconsistent with the fact of the destruction of the Behring Strait whaling fleet by ice. But what do all these groping ideas point to but the adoption of Weyprecht's scheme, advocated by the German Government, and curiously enough only now finding its way into the daily papers, as something before quite unknown here, though we published it in detail a year ago. If we are not mistaken we shall have to thank both the successes and the failures of this expedition for opening up a new era in Arctic exploration. The following promotions for services rendered in connection with the Arctic Expedition have been made:—Commander A. H. Markham to be Captain; Lieutenants Pelham Aldrich, L. A. Beaumont, and A. A. C. Parr to be Commanders; Sub-Lieutenant C. J. M. Conybeare to be Lieutenant; Staff-Surgeon B. Ninnis, M.D., to be Fleet Surgeon; Surgeons E. L. Moss, M.D., and R. W. Coppinger, M.D., to be Staff Surgeons; Engineers D. Cartmel and James Wootton, to be Chief Engineers; Assistant Paymaster Thomas Mitchell to be Paymaster.

AS we announced last week, Capt. Allen Young has returned with the *Pandora*. He was so beset with ice in about 78° N., that he was able to accomplish little, though he managed to deposit the letters and despatches which he took out for the expedition. Capt. Young found some Eskimo at the high latitude of 77° 12′ N., who conducted themselves very well. They offered Capt. Young's party everything they had, and when asked what they would like to receive, the chief went off to the ship and selected a 15-foot ash oar and some gimlets. He wanted the oar for spear shafts, and the gimlets to bore ivory and bone in order to cut it. Some other useful presents were given them, and they gave in exchange some narwhal's horns, specimens of their pot stone cooking kettles, and of the iron pyrites used for striking fire. Capt. Adams, the well-known master of the whaler *Arctic*, has brought home with him to Dundee an Eskimo "Chief" named Alnack, thirty-eight years old, who has for years begged to be taken to England. His object in coming to Dundee is that he may get during the winter, knowledge that might be of much importance to the tribe of which he is chief. We hope he will take more kindly to our climate and habits than previous Eskimo visitors.

THE following is the award of medals for the present year by the Council of the Royal Society:—The Copley Medal to Prof. Claude Bernard, For. Mem. R.S., for his numerous contributions to the science of physiology; a Royal Medal to Mr. William Froude, F.R.S., for his researches, both theoretical and experimental, on the behaviour of ships, their oscillations, their resistance, and their propulsion; a Royal Medal to Sir C. Wyville Thomson, F.R.S., for his successful direction of the scientific investigations carried on by H.M.S. *Challenger*; the Rumford Medal to Mr. Pierre Jules César Janssen, For. Mem. R.S., for his numerous and important researches in the radiation and absorption of light, carried on chiefly by means of the spectroscope. The medals will be presented at the anniversary meeting of the Society on the 30th inst. It is hoped that the two eminent Frenchmen named in the foregoing list will be able to appear in person on the day appointed.

THE store-houses, workshops, and studies of zoology of the Jardin des Plantes, Paris, have been recently removed to a new and most commodious building in the rue Buffon, where there is ample space for scientific work of every kind. Plans have likewise been made for the erection of a large new building in front of the "Galerie," in order to give more space for the exhibition of the general collection of zoology.

RUSSIAN newspapers announce the death of M. Chekanoffsky, who, exiled in Siberia, has spent more than ten years in the geological exploration of the country, and recently returned from his travels on the Olenek and the shores of the Polar Sea, to St. Petersburg, where he was engaged at the Academy in the description of his immense collections. He was found on October 10 dead in his room, and it is supposed that he poisoned himself.

THE Academy of Geneva, whose foundation goes back to the sixteenth century, to the time of Calvin and Beza, has for more than three centuries maintained a renown and a value far exceeding the dimensions of the small republic which glories in its prosperity. Five years ago, in consequence of the erection of large buildings for its use and of concomitant legislative decisions, it assumed the title of University, the National Council having decreed the creation of a Faculty of Medicine as an addition to those of ancient standing. Until now this new faculty existed only on paper, the buildings intended to receive it not having been erected. They have been recently finished; the professors have been chosen from the native medical men, to whom have been added some eminent foreigners—Professors Schiff, of Florence, Zahn, of Strasburg, and Laskowski, of Paris. An inaugural ceremony took place on October 26, when addresses were given by the President of the Council of State, the Rector of the University, and the Dean of the new Faculty. There are already fifty students, and the organisation of the new classes has been made on a scale entirely satisfactory.

THE *Norddeutsche Allgemeine Zeitung* states that Capt. Kielsen, of the *John Maria*, Tromsoe, has reached 81¼° N. lat. between Novaya Zemlya and Spitzbergen, and found the sea free of ice. He discovered an island with a mountain 500 feet high, which he called White Island. He supposes that the ice-wall round the Pole was, at least this year, at a higher latitude, and that the Gulf Stream generally follows this direction.

THE following statistics with regard to the number of students attending German universities during the summer term of this year are taken from the just published *University Calendar* for 1876-7. Berlin—number of students, matriculated and unmatriculated—3,666, of teachers 193. The corresponding numbers in Leipzig were 2,803 and 155; Munich, 1,158 and 114; Breslau, 1,1[illegible] and 108; Göttingen, 1,059 and 119; Tübingen, 1,025 and 86; Würzburg, 990 and 66; Halle, 902 and 96; Heidelberg, 795 and 110; Bonn, 785 and 100; Strasburg, 700 and 94; Königsberg, 611 and 82; Greifswald, 507 and 60; Jena, 503 and 77; Marburg, 445 and 69; Erlangen, 422 and 55; Münster, 415 and 29; Giessen, 343 and 59; Freiburg, 290 and 54; Kiel, 223 and 65; and Rostock, 141 and 36. Of universities outside the German Empire, Vienna had 3,581 students and 247 teachers; Dorpat, 844 and 65; Graz, 804 and 88; Innsbruck, 570 and 67; Zürich, 355 and 78; Bern, 351 and 74; and Basel, 239 and 64.

IT is proposed by the Council of the Trades' Guild of Learning, in conjunction with the Committee of the National Health Society, to organise a course of twenty lectures on the "Laws of Health," to be delivered by W. H. Corfield, Professor of Hygiene and Public Health in University College, London, in the large room of the Society of Arts, John Street, Adelphi, W.C., on consecutive Saturdays, commencing November 11, at 8.30 P.M., excepting the following dates:—December 1 (Friday), February 1 (Thursday), March 1 (Thursday). There will be an interval of four weeks at Christmas, and three weeks at Easter. Certificates will be awarded to those who satisfy the examiner and who have attended not less than fifteen lectures out of twenty.

MR. MCMANN writes that on p. 18, vol. xv., in, our notice of his method of comparing spectrum maps, E should have been G. The distance between B and G is not assumed equal to 100, he states, but is assumed equal to 1, and is divided into 100 equal parts.

IN a letter addressed to Dr. Andrews, Prof. Wartmann, of Geneva, states, with reference to the communication on Radiometers to NATURE of Oct. 19, that Prof. Frankland reproduces precisely the conclusions which Prof. Wartmann gave at one of the conferences at South Kensington in the month of last May. The results were published in No. 222. (June 15) of the *Archives des Sciences Physiques et Naturelles*. In the first note which Prof. Wartmann published (*Archives*, No. 219, March 15) he said (p. 315) that by making two calorific sources act simultaneously on the opposite faces of the same disc, we obtain an equilibrium when the intensity of the pressures is in the inverse ratio of the absorbing power of each face. The experiments, which he made in spring, during very favourable nights, on the nullity of the action of the lunar light, completed the demonstration. It is the calorific radiation which is the cause of the movements of the radiometer.

AT the recent meeting of the German Association of Naturalists and Physicians, Dr. Hermes described some interesting characteristics of the young gorilla in the Berlin aquarium. He nods and claps his hands to visitors; wakes up like a man and stretches himself. His keeper must always be beside him and eat with him. He eats what his keeper eats; they share dinner and supper. The keeper must remain by him till he goes to sleep, his sleep lasting eight hours. His easy life has increased his weight in a few months from thirty-one to thirty-seven pounds. For some weeks he had inflammation of the lungs, when his old friend Dr. Falkenstein was fetched, who treated him with quinine and Ems water, which made him better. When Dr. Hermes left the gorilla on the previous Sunday the latter showed the doctor his tongue, clapped his hands, and squeezed the hand of the doctor as an indication, the latter believed, of his recovery. In fact the gorilla is now one of the most popular inhabitants of the Prussian capital. For Pungu, as the gorilla is called, a large glass palace has been erected in the Berlin Aquarium in connection with the palm-house.

THE *Kölnische Zeitung* of November 4, reports on the discovery of an ancient burial ground, during some excavations made near Rauschenburg on the Cologne-Minden Railway. It appears that a number of antiquities were found, and while the vases amongst them, as well as a number of objects found in these vases are of undoubtedly Roman origin, it is doubted that the people buried there, and whose skeletons were found, were of Roman nationality. It is believed at present that they were Teutons of the third or fourth century who lived in friendly intercourse with the neighbouring Romans, and had obtained from them the objects mentioned. A definite opinion would be premature until the whole of the ground is excavated, and a scientific investigation has been made of all that is found. Amongst the objects discovered recently, we may mention a well-preserved vase of *terra sigillata*. On its floor there is still a small remainder of the linen containing the bone-ashes; the vase is 20 cm. broad, and 12 cm. high; it shows an ornament which is of decidedly Roman origin. Amongst the bone ashes in its interior there were two bronze nails, several molten pieces of bronze, and remains of a beautifully ornamented ivory comb. Another vase, quite full of bone ashes, and roughly worked of coarse clay, consists of two parts almost equal, of which the lower one is 25 cm. broad, and 16 cm. high, while the upper one is 27 cm. broad, and 18 cm. high. Amongst the bone ashes it contained were found several molten pieces of bronze, the remains of a burnt ivory comb, and a piece of some handsome ornamental object made of bone. Round this urn several smaller vessels were placed; they were of ordinary gray clay, two of them of somewhat finer black clay. One of them was empty, another one contained ten little pieces of clay, about 3 cm. thick, and perforated, all of different shapes, they had very likely been worn as beads on a string round the neck. There was also a little tablet of bronze in this vessel. One of the black vessels seems to have served for incense, the other one may have served the same purpose, but being shaped like a three-armed Roman lamp, it is probable that it served as support for three lamps. Of the different pieces of undoubtedly Roman vases that were found besides the above, one shows the figure of a hare, and another that of a running hound—both in relief.

A WISH, which was expressed last year at the International Geographical Congress held at Paris, will be realised in January next. From that date a monthly geographical review will be published there, at the Libraire of Ernest Thonin, and edited by Ludovic Drapeyron, Professor at the Lycée Charlemagne, and member of the Academie. This *Revue Geographique* will contain reports of all work done in connection with geography; the investigation of the various methods now employed in teaching geography, as well as topography, will form some of the principal subjects of the *Revue*. Besides theoretical original papers, it will publish the latest reports of the different travels of discovery going on in various parts of our globe, criticism on new geographical works, biographies of celebrated geographers, &c. The *Revue Geographique* is not to be the organ of petty party spirit, but of all those who see in geographical science one of the principal means of breaking the reign of empty rhetorics and scholastica. Besides geographers and geologists, the editor invites for co-operation the representatives of all historic sciences in the widest sense of the term—palæontologists and ethnographers, as well as archæologists—all those, therefore, who by the application of geography in historic research, wish to open new fields for social science in general.

THE University of Zurich has announced that in future, like the German universities, it will grant the doctor's degree only after an oral and written examination.

MR. BRYCE M. WRIGHT, of Great Russell Street, has procured one of the finest and most complete specimens known of the Plesiosaurus from the Lias of Whitby, which is open to the inspection of the public until the 12th inst. The neck is 6½ feet long, and the entire animal nearly 17 feet. The whole of the vertebræ from the head to the tip of the tail are complete without the slightest break, which gives some idea of the entirety and preservation of the animal. It was procured from the cliff in which it was found in about twenty pieces, but after three weeks' incessant work Mr. Bryce Wright has mounted it in such a manner that one could scarcely believe a bone had been disturbed. Mr. Bryce Wright, has, we believe, secured this specimen for a foreign institution.

THE additions to the Zoological Society's Gardens during the past week include a Puma (*Felis concolor*) from Santa Fé, presented by Miss Brassey; two Wild Swine (*Sus scrofa*) from Cuba, presented by Mr. J. Alfonso de Aldama; a Persian Gazelle (*Gazella subgutterosa*) from Persia, presented by Mr. T. Fowler; two Senegal Touracous (*Corythaix persa*) from West Africa, a Sun Bittern (*Eurypyga helias*) from South America, a Scarlet Ibis (*Ibis rubra*) from Para, a Ring-necked Parrakeet (*Palæornis torquata*) from India, two Black Tortoises (*Testudo carbonaria*), a Common Boa (*Boa constrictor*) from Panama, a Sulphur-breasted Toucan (*Ramphastos carinatus*) from Cartagena, deposited; an Andean Goose (*Bernicla melanoptera*) from Chili, purchased.

SOCIETIES AND ACADEMIES

PARIS

Academy of Sciences, October 30.—Vice-Admiral Paris in the chair.—The following papers were read:—Letter of Mr. Hind communicated by M. Leverrier, on the intra-Mercurial planet.—Study of the organs of reproduction in ephemera, by M. Joly.—On a new electric lamp devised by M. Sabloschkoff, by M. Denayrouze. The carbons are fixed parallel, and the short interval between them is occupied by an insulating substance which disappears along with them (as the wax of a candle used, sand, glass, mortar, lac, &c. The simplest and cheape is a sand of pounded glass.—On the distribution of magnetis on the surface of magnets, by MM. Trève and Durassier. T more a steel is carburetted, the more is the magnetism co densed towards its extremities; the less carburetted, the more magnetism spread out equally over its surface. The authors a having a series of steels prepared by hardening with cold wate and they seek to formulate a simple law establishing the relati between the coercitive force and the proportion of carbon.—C the deterioration of vineyards of Côte-d'Or, by M du Mense —M. Wery submitted an apparatus for ventilating apar ments and mines, or increasing the draught of chimneys.—O the rotatory polarisation of quartz, by MM. Soret and Sarasi They extend their observations to the ultra-violet rays mo refrangible than the line N, and also make more precise measure ments. The results are tabulated.—On the laws of vibrator motion of diapasons, by M. Mercadier. The number of vibr tions of a prismatic diapason is proportional to its thickness an inversely as the square of its length. The isochronism of vibra tions is not absolutely rigorous; the duration of the period depend on the amplitude and the temperature. In using a diapason a chronograph or interrupter, the instrument will not give re sults quite identical unless you operate at the same tempe rature and give the vibrations the same amplitude. If (as i generally the case) one does not need complete identity and larg amplitudes, then provided an amplitude of 2 to 3 mm. be no exceeded, and one operate at temperatures little different, one i certain to have the same number of periods per second to nearl 0·0001.—Chemical reactions of gallium, by M. Lecoq de Boisbaudran. *Inter alia*, further experiment confirms the opinion that oxide of gallium is more soluble than alumina in ammonia Carbonate of soda only precipitates indium after gallium. Chloride of gallium is very soluble and deliquescent. A slightly aci solution of it dried at a mild heat, gives needles or crystallin lamellæ, which act strongly on polarised light. Sulphate of gallium is not deliquescent.—On terephtalic aldehyde, by M. Grimaux —On the simultaneous formation of two trioxyanthraquinones an the synthesis of a new isomer of purpurine, by M. Rosenstiehl.—On the electric apparatus of the torpedo (third part), by M Rouget. In the electric discs, besides ramifications of nerve fibres and the reticulated nervous plate, one finds only vessel and cell-elements, fibrillæ and membranes belonging all to th connective tissues. M. Rouget offers a theory as to the mechanism by which the nervous elements produce electrical effects —On the phenomena of division of the cellular nucleus, by M. Balbiani.—Variations of the electric state of muscles in tetanus produced by passage of a continuous current, studied by mean of the induced contraction, by MM. Moral and Toussaint. I such tetanus the induced contractions (shocks, isolated or associated into a tetanus of short duration) are to be regarded a accidents, though the comparison of the two traces (inducer an induced) indicates but imperfectly the cause of these accidents The electric state of the muscle is sensibly uniform during th whole duration of the contraction.—On some parts relating t nutrition of the embryo in the egg of the hen. The blastoderm derives its elements from the yolk, whereas at the beginning o incubation, and at least till the time of complete closure of th amnion, the embryo is developed at the cost of the albumen.—On the influence of poisoning by the bulbous agaric on glycæmi by M. Oré.—On the employment of picric acid in treatment o wounds, by M. Curie.

FOSTER'S "ELEMENTARY PHYSIOLOGY"

A Course of Elementary Practical Physiology. By M. Foster, M.D., F.R.S., Fellow of and Prælector in Trinity College, Cambridge, assisted by J. N. Langley, B.A., St. John's College, Cambridge. (London: Macmillan and Co., 1876.)

In this little book Dr. Foster gives us the results of his experience in teaching physiology practically to students. As may be readily understood, such teaching is attended with much greater difficulties than those encountered in the experimental teaching of chemistry or of physics—difficulties which arise partly out of the complexity of the phenomena to be demonstrated, partly from the circumstance that experiments in which living processes are concerned cannot be repeated so frequently as would be desirable. Dr. Foster has himself been remarkably successful in overcoming these difficulties. The evidence of that success is to be found in the number of men whose names are already known as efficient workers in physiology, who owe to his teaching their first introduction to scientific research. On this ground, even more than on that of his long experience as a teacher, his opinion on the question of method is more worthy of attention than that of any other person. The book is entitled "A Handbook of Practical Physiology." Our readers are probably not aware that during the last half-dozen years that term has acquired a special meaning. Under the term Practical Physiology all students of medicine are now required by the examining Boards to go through a course of laboratory instruction, for which accordingly arrangements are made in all medical schools. In very many instances the instruction is purely technical and anatomical. All that is attempted is to teach the student "how to work with the microscope," which means for the most part how to prepare tissues for microscopical examination. The acquirement of this art, although, it need not be said, of great value to the physiologist, is not the end and purpose of physiological teaching. The physiologist interests himself only in what is living, and when he uses the microscope, concerns himself with the anatomical structure of a part or organ, only in relation to its living properties.

The handbook contains no description of the microscope, and the subject of microscopical manipulation is dealt with in an appendix. In this respect it differs from most previously published works on histology. Nevertheless it is as good an introduction to that subject as the beginner in animal physiology can take in hand. The plan of study laid down is anatomical, but in carrying it out, the principle is acted upon that it is desirable from the first to give meaning and interest to the otherwise dry details of anatomy, by combining the study of the function of every part with that of its structure. Histological work, says Dr. Foster in his preface, "unless it be salted with the salt either of physiological or of morphological ideas, is apt to degenerate into a learned trifling of the very worst description." To avoid this evil, of which the feebleness of English microscopy is the best evidence, Dr. Foster encourages the student, as soon as he has learnt the anatomy and histology of a part, to pass at once to its physiology, "so that by learning what is known concerning its action, he may form an opinion of the real importance of its structural details."

Let us now see how the principle is carried out. The book comprises twenty-nine lessons. The first is entitled, "Dissection of a Rabbit and of a Dog." The purpose of this introductory lesson is to make the student acquainted with the general construction of the body of the mammalian animal as a whole, a sort of knowledge which students of human anatomy are often strangely wanting in. Then follow two lessons on the blood. In the first, the student learns all that relates to the structural elements of the circulating fluid; but even here the instruction given is of such a nature that he cannot fail to be impressed, provided that he is capable of being impressed by observation, with the fact that he has to do, not with dead forms, but with living organisms. In the second lesson on the blood, the chemical constituents of the *liquor sanguinis* are dealt with, particularly those which are concerned in the process of coagulation. Here necessarily, the microscope and scalpel are for the moment replaced by methods and instruments borrowed from the chemical laboratory, but they are resumed in lessons four and five for the study of cartilage, bone, teeth, and the connective tissues. In the next series of lessons on contractile tissues, structure and function are again mixed. The student, as soon as he knows what cilia and muscular fibres are like, at once proceeds to find out for himself, though according to a prescribed order, how they work. He familiarises himself in succession with the effects of the voltaic current, of single induction shocks, and faradization on living muscle, then proceeds to the more minute examination of the mechanical phenomena of muscular contraction, and finally, as in the previous study of the blood, investigates the same phenomena in their chemical relations.

In the same style and on the same principle each successive subject is dealt with. "The animal body is regarded," to quote the author's words, "as a collection of fundamental tissues, each having a conspicuous property or properties."

Each lesson has appended to it a list of subjects for demonstration by the teacher, these consisting either of microscopical structures requiring very high powers for their exhibition, or of experiments which the student would be unable to perform for himself. Among these last only such are comprised as are in their nature painless.

There can be no doubt that the book is admirably adapted for its immediate purpose, namely, for the instruction of natural science students at Cambridge. In order to judge of its general utility the question must be asked whether it is adapted to the requirements of the much larger class of students who learn physiology with a view to the study of medicine.

The answer to this question must depend on the class of medical students contemplated. Students of medicine may be divided into three categories, the first comprising those who come up with the avowed intention of acquiring no more than the minimum of cram exacted of them by the Examining Boards, and who at the end of their time are as incompetent for practice as they are destitute of knowledge. The second, and by far the largest class, made up of men who, while they desire to acquire by assiduous reading as much so-called medical science as is thought necessary for them to possess, rightly regard it as their principal duty to devote their energies during their brief period of study to the attainment of skill and experience in the arts of medicine and surgery. But besides these, there is a smaller class of men who not only have time for real study, but possess the necessary previous education in which their fellows are in general so deplorably wanting, and whose motive for work is something higher than that of preparing themselves for examination.

To medical students of this last class the lessons are perfectly adapted. Nor can we conceive that a better course could be followed by a young man intending to fit himself for the higher career of the medical profession, than that laid down by Dr. Foster, namely, that he should at a very early period, *i.e.*, while he is still engaged in the study of the more exact branches of natural science, first work through the course of elementary biology laid down for him in the well-known lessons of Professor Huxley; then that he should devote a considerable proportion of his time during a subsequent year to becoming conversant with the structures and processes peculiar to the bodies of the higher animals, under the guidance of a teacher who must be a real physiologist—all this being accomplished before he begins his proper medical studies, *i.e.*, before he begins to study the details of human descriptive anatomy.

Strange as it may seem, it is not yet sufficiently recognised by those who are concerned in medical education that the men on whom the community depends for enlightenment on the great questions of the preservation of health and the prevention of disease, ought to be practically familiar with all that is known concerning living processes. The remark is frequently made that even to the consulting physician or to the officer of health, physiology and pathology are of relatively little value. Surely this must be a mistake. It may be readily admitted that the ordinary practitioner needs only familiarity with the characteristics of human ailments and the prescribed methods of treatment and skill in the handling of sick people, and may well content himself with as much of the elements of scientific knowledge as he can learn from manuals and lectures; but surely the education of those who are intended to be advisers of the public in relation to health and disease should have some more solid foundation. There can be no question that these men ought to be prepared for their higher functions and responsibilities by such a course of preliminary work in physiology as will enable them, if so be that nature has fitted them for it, to enter with some hope of success on those most difficult of all biological investigations which relate to the nature and causes of diseases.

BRITISH MANUFACTURING INDUSTRIES

British Manufacturing Industries. Edited by G. Phillips Bevan, F.G.S. "Salt, Preservation of Food, Bread, and Biscuits," by J. J. Manley, M.A.; "Sugar Refining," by C. Haughton Gill; "Butter and Cheese," by Morgan Evans; "Brewing, Distilling," by T. A. Pooley, B.Sc., F.C.S. (London: Edward Stanford, 1876.)

THE preface states that in these volumes, of which the present is one, "the facts are gathered together and racy and a freedom from superficiality; and though they do not lay claim to being a technical guide to each industry, the names of the contributors are a sufficient guarantee that they are a reliable and standard work of reference."

This editorial explanation fairly describes the scope of the articles contributed by their respective writers to this volume; since, while not pretending to be a technical guide to each industry, they must prove of great value to all desiring to obtain a *general* knowledge of the processes described. The common fault of encyclopædias of this kind is to devote much space to detailed explanations of manufacturing processes and of the machinery employed. To the ordinary reader all such elaborate details are useless, since his object is to obtain information upon the general principles upon which the various processes are based; and to the manufacturer practically engaged in any process they are equally useless, since no matter how carefully written, they can teach him nothing, because, as a matter of course, he is in advance of the processes described with so much detail.

The first article is an interesting account of "Salt," where found, and how manufactured from the crude deposit. Some valuable statistics are given as to the quantity produced in and exported from England.

The next article on the "Preservation of Food" by the same contributor deals with a subject of increasing importance. Though there has been an important increase, of late years, in the amount of green crops, and in land laid down to grass in the United Kingdom, yet the consumption of beef and mutton has so spread among the working classes, as to render the increased production vastly inadequate to the ever-increasing demand. It has become in consequence a matter of the highest importance to discover means by which animal food may be imported from America, Australia, and other countries where it is abundant.

The chief processes hitherto employed for the preservation of meat are classified by the author under the heads of Drying, Action of Cold, Chemical Reagents, and Exclusion of Air. The drying process has certainly not proved a success. "Charqui," so much praised a few years since, is but a poor substitute for fresh animal food.

The value of ice in preserving meat in cold countries is so well established, that it naturally presents itself as a convenient agent. Hitherto, however, as regards great distances, it has failed. This has arisen from two causes: in the first place the temperature of melting ice is not low enough to prevent change even on ship board; this difficulty will doubtless be overcome by the employment of machines, by which a temperature lower than 0° C. can be maintained at sea. Another difficulty has arisen from the fact that meat kept at the temperature of melting ice is very prone to change so soon as removed from the ice-tanks to be distributed throughout the country. Doubtless in time these and other difficulties will be removed, and our large cities, at least, be supplied with regular arrivals of fresh uncooked meat from South America and our colonies.

The use of chemical reagents has hitherto proved inefficient, but we cannot agree with Mr. Manley "that it is hardly likely that the use of chemicals will solve the question of meat preservation." A patent has lately been
by which oxygen-absorbing reagents are so suc-

cessfully applied as to give some hope that this or some other chemical process will aid us in this important question.

The author gives some useful details and statistics regarding the "tinned meat" process. This well-known method depends upon the exclusion of air by the substitution of steam, and in the consequent destruction of organic germs. So far as mere preservation is concerned, it has undoubtedly proved a great success, and has already been of some benefit to us; but the long cooking process hitherto employed to expel the air has so destroyed the texture of the meat as to have rendered its use unpopular in spite of the efforts of enthusiasts to force the over-cooked product upon an unwilling public. So soon as the very primitive plan of heating the tins in a bath of chloride of calcium for three or four hours be replaced by one exhausting the air and replacing it by steam at a high temperature successively, and occupying no more than half an hour, then will the tinned meat process prove a real success, and possess many advantages over all others. Mr. Manley has done good service by his description of what has been attempted, and though he suggests but little himself, he may induce some of his readers to experiment upon a matter of such national importance.

The paper on "Sugar Refining" is one of the best contributions in the series, written by one not only an able chemist but also a thoroughly practical sugar refiner. As a clear, accurate, and scientific exposition of an important industry it serves as an example of what such contributions should be. Its only fault is that it is somewhat too brief. After the usual historical account of the industry, the author explains the more important properties of sugar, and shows how these are made use of in the various stages of extraction and purification from the cane and the beet. The author has not considered it within his province to refer to the serious injury to our sugar manufacturers by the heavy export premiums paid by the French nation on all high class products exported to this country. Doubtless so soon as the French financiers have completely extinguished the manufacture of loaf and other high class sugars in England, they will then remove the export premiums, being full well assured that the memory of the ruined English sugar refiners will for a long time at least deter our capitalists from competing with French refineries. Though the "beet" produces one-third of the total amount of sugar grown, and has proved of such value to agriculture on the Continent, yet hitherto the growth of beets for sugar manufacturing purposes has not proved a success in our own country. Nor indeed is it likely to prove remunerative so long as it pays better to grow beef and mutton. In concluding this brief notice we cannot refrain from once more praising the author's valuable—though brief—contribution.

Mr. Evans contributes a short article on dairy produce. He gives some interesting information upon the factory system of cheese-making introduced with so much success into England within the last few years. It is to be regretted that Mr. Evans has given no information upon the mode of preparing the French, Italian, and Swiss cheeses so much appreciated by connoisseurs.

The article on "Brewing and Distilling" is a useful contribution on two important industries, by one evidently well acquainted with them. Some valuable statistics are given, showing the vast development which has taken place in the production of alcoholic beverages in the United Kingdom. According to the author, on March 31, 1873, there were 31,010 brewers, 144,425 dealers and retailers of beer. The income derived from beer in 1873 amounted to 8,027,408*l.*, a sum which fully explains the hesitation of the present Government to please the agricultural interest by the removal of the malt-tax. In addition to these thirty thousand brewers, of whom, however, only some three thousand are licensed common brewers—there are, it appears, 318 distillers and rectifiers, producing 30,644,750 gallons of spirit, yielding a revenue of 14,895,769*l.*; the number of licences issued in 1875 to persons dealing in and retailing spirits was 138,845. The author calculates that in the brewing and distilling industries, and in those originated and sustained by them, there is a capital of two hundred millions invested. Without following Sir Wilfrid Lawson in all his statements, one cannot but view an annual consumption of twenty-eight to thirty millions of gallons of spirit as a most serious feature in our social life.

Those interested in this matter and desirous of obtaining a general knowledge of the technical processes, will with advantage consult Mr. Pooley's articles. In concluding this notice of the volume before us we must congratulate the publisher and the editor on their success in obtaining the aid of writers so well acquainted with their respective subjects.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*]

Sea Fisheries

MR HOLDSWORTH, at the close of his animadversions (NATURE, vol. xv. p. 23) on the address I recently delivered in the Biological Section of the British Association at Glasgow, says that he does not know on what evidence I grounded my belief in the decline of our sea-fisheries. I am therefore anxious to state that the evidence to which I trusted in what I then said was mainly, if not entirely, that collected by the Royal Commission of which he was the hard-working secretary. The kindness of my good friend in giving me private notice of his intention to make his comments public enables me the more promptly to furnish a reply to them, and for so doing he has my best thanks.

I do not pretend to have read through the whole of the 1,500 and odd somewhat closely-printed folio pages which form the two "Blue-books" embodying the labours of that Commission. But soon after they appeared—about ten years ago—I looked into them sufficiently, as I thought, to give me a fair notion of their contents. Whether that notion was mistaken your readers will be better able to judge by the time I have done. When I wrote my address I had not these books by me. I have since refreshed my memory by consulting them. I find that deep as was the impression left by my first examination of them it is now still deeper, and were I to write my address over again I should express myself in far stronger terms.

The second and most bulky volume of these blue-books contains the "Minutes of Evidence" taken before the Sea Fisheries Commission, and reports the 61,831 questions and answers put by or given to the Commissioners. At first the attempt to find the particular needles one may be seeking in this immense bottle of hay seems hopeless. But fortunately the volume (as most blue-books are) is furnished with a copious index, extending to 29 pages folio, and by help of this I beg leave to submit to Mr. Holdsworth and your readers the following results.

The Commissioners took evidence at eighty-six places (Billingsgate and London counting separately), which, for convenience' sake, I will call "stations." Now it appears that of these eighty-six stations evidence was offered at twenty-two, showing an *increase* in the supply of fish generally, and evidence showing a *decrease* at forty-three, or exactly half of the whole number. But at thirteen of these stations the evidence was conflicting. Deducting, therefore, that number from each side, we have thirty stations where the evidence was solely for the decrease and only nine for the increase, or a clear majority of twenty-one stations for the former. It also appears (unless my arithmetic is at fault) that of the answers given to the Commissioners at these several places 250 showed an increase, and 605 a decrease. If, then, my opinion on this subject is so erroneous as Mr. Holdsworth asserts, it is one entertained by a good many people who know more of fishery matters than I do.

If, further, we analyse the evidence as to various kinds of fishes the results will not be very different. These will be best stated in a tabular form.

Kind of !	No. o' Stations showing					
Brean						
Brill			2			
Cod and Ling ...	9	—	42			
Dogfish	—	—	2	—	—	2
Haddock	12	—	40	10	4	38
Hake	1	—	13	—	—	12
Halibut	—	—	2	—	—	2
Herring	24	—	41	—	13	17
Ling	1	—	8	—	1	7
Mackarel	4	—	11	—	2	7
Megrim	—	—	—	1	—	1
Pilchard	3	—	1	—	—	—
Plaice	3	—	2	—	—	—
Pollack	—	—	—	3	—	3
Skate	—	3	—	—	—	—
Smelt	—	—	2	—	—	2
Sole	6	—	15	—	2	9
	3	—	6	—	1	3
	7	—	9	—	—	2
	6	1	11	—	—	4

Thus out of these *twenty* kinds, *sixteen* show a positive decrease at more or fewer stations, and among them are some of the most important of our "food fishes"—cod and ling, haddock, hake, herring, mackarel, sole, sprat, and whiting.

Now I can imagine *three* objections being raised to the obvious inference from this table :—

First: that the witnesses for the decrease were untrustworthy.

Secondly: that the Irish stations are included among those showing decrease, and Irish fisheries are said to be languishing from causes which do not concern the present matter.

Thirdly: that even the non-Irish stations showing decrease are comparatively small and unimportant.

1. Without imputing any want of veracity to the witnesses for the decrease it is obvious that, as all fishermen have a pretty hard time of it, the proportion among them with a despairing turn of mind may be greater than among men who follow other callings, and that this may unconsciously tinge their testimony. So far, however, as my own experience goes, which is perhaps a very little way, I have found that the grumblers among fishermen commonly assign some specific cause for their complaints—be that cause real or imaginary. If so-and-so were or were not the case, they say, they would get on very well. Their assignment of any cause is purely a matter of opinion with them. Their statements as to the increase or decrease of fishes relate to a matter of fact within their own knowledge.

2. The proportion of Irish to non-Irish stations among those which show decrease is by no means excessive. Here it is :— out of 13; herring, 10 out of 41; mackarel, 2 out of 11; sole, 1 out of 15; sprat, 1 out of 6; whiting, 1 out of 11. If the Irish stations were wholly disregarded the general deduction would not be materially affected.

3. Any one who has ever tried to learn the facts attending the process of extinction of animals, will soon find that the premonitory symptoms of approaching extirpation may be for a long time hardly recognisable at places where the particular species concerned is most abundant. It is first cut short on its borders, and scarcity begins and is most readily perceived at its outlying localities. Hence it is exactly in accordance with what always, or almost always happens, that the smaller and least important fisheries should first show signs of decline, if such decline is going on, as the above figures seem to prove. It may be years before the great trawling-grounds on various parts of the coast, or the Dogger Bank and the Silver Pit show unmistakable signs of exhaustion, but where is the take of fish inshore increasing or even stationary?

Having thus furnished the main grounds of my belief—for I do not wish to rely on the Report of the Committee of the House of Commons in 1833 (though that declared the Channel fisheries to have been in a declining state since 1815) further than to show it is a belief of long standing and held by practical men—I must proceed to make some other remarks on Mr. Holdsworth's indictment. First of all let me admit that he is of course literally accurate in his statement of the particular objects for which the Royal Commission of 1863 was appointed. But, as he also rightly remarks, its inquiry was extended, and indeed no one can glance at its blue-books without seeing that the inquiry covered far more ground than ever was scraped by a trawl. As I read the Instructions to the Commissioners, they were wide enough to permit any sort of inquiry into British Fisheries—even the seeking of a remedy for any decline in them if such was found to exist. But since my friend takes refuge behind the literal wording of the Queen's Commission, I may do the same with regard to the expressions used in my address. No doubt had I had the blue-books by me when I was writing I should have been more explicit in separating the Commission in which he acted as secretary from others that had preceded it. But, as it is, my words, reprinted in your own columns (NATURE, vol. xiv. pp. 440, 441), show that I spoke of it as something distinct from them, and so it truly was, for as Mr. Holdsworth himself says, it was "the most comprehensive investigation of the subject that had ever been made," and the evidence it collected is one of the most valuable contributions to applied zoology with which I am acquainted.

Next there comes up another point. It is quite compatible with an increased *supply* of fish that there may be an actual decrease in the *stock* of fishes, and it seems to me that my critic hardly sees the danger of confounding these two very different things. That the supply of fish to our markets has of late enormously increased may be indubitable—the question really is whether there are still in our seas as many fishes as there used to be. The evidence I have above analysed shows, I think, that there are not, and the recommendations of the Commissioners of 1863 are certainly not such as would increase the number.

Mr. Holdsworth asserts that "practical mischief is likely to result" from my opinions becoming known to fishermen. I wish he had been a little more careful to explain wherein the danger lies. Unless it be that the next Sea-Fisheries Commissioners may find their inquiries suddenly stopped by a well-placed torpedo, I am at a loss to imagine the risk. As, however, their permanent brethren of the Rivers Commission continue to pursue their duties without any such unpleasant consequences, I think the possible mischief must be over-rated. Mischief may arise, though, from the utterance of smooth sayings, and very great mischief too; but, if it does, it will not attach to those that utter the note of warning. My friend refers to his "Deep-sea Fishing and Fishing-boats," an excellent work in many respects, which fully deserves all that was said in its praise in your columns when it appeared (NATURE, vol. xi., p. 421), and perhaps more, for the reviewer did declare that the author's "inferences and his facts are very much at variance," which was perhaps going rather too far. I have carefully read it, but I fail to find there any new facts—new, I mean, since the publication of the blue-books before-mentioned—that bear out his views of the matter. On the contrary, I have met with several admissions which I think point in the opposite direction. Thus I read of Yarmouth (p. 111) :—"The mackarel 'voyages,' however, have been so unprofitable during the last few years that there is little inducement to invest very largely in new gear for that fishery."

A little further on, of Lowestoft (p. 122) :—"Recent experience, however, does not support this statement" [that the summer fish are often as abundant as they ever were before the spring-fishery came into fashion], "as with a more or less successful series of spring fisheries, the summer herrings have been exceedingly scarce for the last seven years." Now neither Yarmouth nor Lowestoft are very small or unimportant stations. It would look, then, as if scarcity has begun to appear there. Again (pp. 214, 215), Mr. Holdsworth tells a very good story of the disappearance of herrings from the Guernsey waters; but he does not contradict the statement that there has been no herring-fishery there since the year 1830. Furthermore he says (pp. 266, 267) :—"Turbot or 'bratt' nets are successfully worked by the Staithes fishermen, although, according to their report, the catches are not nearly as large as they were formerly. This is the general statement along this coast. . . . It is a remarkable circumstance that nearly thirty years ago turbot became so scarce near North Sunderland, close to Holy Island, that the turbot-nets were given up. At that time trawling in the North Sea was only just beginning from Hull and that part of the coast; and the trawlers have never worked near the place where the decrease of turbot was said to have been greater than even at Staithes. It is evident, then, that we have a good deal to learn about what attracts or drives away the fish to or from any particular locality."

To this last remark I cordially agree, for in my address I said that the consideration of our fisheries is "fraught with unusual difficulties." But while we are satisfying ourselves on this and similar points, I cannot regard with the same complacency as Mr. Holdsworth the increasing outlay of capital in improved boats and fresh fishing-gear, the growing fish-traffic on the railways, or the glories of an enlarged and renovated Billingsgate, arising amid the pious ejaculations of its frequenters. Is that the only market which is to be unaffected by inflation? I derive little comfort in allowing my fancy to run riot over the marble slabs of Cheapside, Bond Street, and Arabella Row, teeming at present with every finny delicacy, and still less when I meet the humble barrow of the East-end costermonger, with its as plenteous and more odorific load. The question is, how long will that abundance last? Incalculably great as the stock of fishes in our seas may be, it must be subject to the same laws as the stock of every other animal. Directly the draughts upon it exceed its natural increase, it must dwindle. The time when that shall happen seems from the evidence before me to be imminent.

Some of Mr. Holdsworth's remarks appear to me irrelevant. I said nothing in my address about "spawning-beds," and therefore to have mentioned the discoveries of Prof. Sars and Herr Malm would have been little to the purpose. But if my friend meant to hint that I did not know that the spawn of some fishes floats in the water during its development, I will content myself by observing that my acquaintance with Scandinavian naturalists and their works began in the year 1855. His reference to the Sea Birds' Preservation Bill also seems to be wide of the mark. But I am sure ornithologists will be thankful to him for information that will show how many of the birds named in that Act commonly prey upon the sea-fishes that come to our markets, and which kinds they take. Perhaps he will also explain why the fishermen of our coasts were so strongly in favour of its being passed. Of the precise direction my efforts took towards that end Mr. Holdsworth, I think, cannot be aware.

NEWTON

Magdalene College, Cambridge, November 3

P.S.—If the remarks I made in my address be well founded, they of course have a general bearing, and will apply to all cases of "over-fishing." Since I wrote the above I have received from my kind friend, Prof. Baird, the United States' Commissioner of Tides and Fisheries, his reports from 1871 to 1875. Therein I find the decrease of the Sea-Fisheries on the Atlantic coast of the United States treated as a fact beyond denial, and "over-fishing" unquestionably assigned as the chief cause of that decrease.

The Foundation of *Zoological* Stations in Heligoland and Kiel

WILL you kindly permit me to say a few words in answer to the letter by which my friend Mr. Balfour expressed his view on the proposed foundation of zoological stations at Heligoland and Kiel.

Mr. Balfour has certainly not been well informed, when he believes the promoters of the future stations in Heligoland and Kiel had intended "to put aside claims of the zoological station at Naples in favour of the two new institutions." In the first place it is expressly stated in their Report that the committee are far from wishing to take away the least support from the Naples establishment. Besides, according to information which reached me some time ago, one of the most competent and influential members of the committee has only consented to act, if it is expressly stated in the memorandum to be handed over to Government, "that, should the empire limit its annual contributions to zoological stations to 1,000*l*. or 1,200*l*. (a sum asked at present for the zoological station at Naples), this sum ought to go *undivided* to the Naples establishment as the one of much greater importance. The foundation of the two northern stations ought in consequence to be deferred to later times."

Nothing more than this could be desired, and certainly the proposition once made, nothing more could be expected, and had Mr. Balfour been acquainted with the whole of the facts, I am satisfied he would never have applied the terms "unwise and ungenerous" to the proposition. He is, however, certainly right in maintaining that the Naples station has been the means of proving both the value and feasibility of such institutions, and perhaps nobody, besides myself, knows better than Mr. Balfour, how great and how numerous were the obstacles which had to be overcome. This and the fact that Mr. Balfour assisted me most generously and most vigorously during the whole of my struggle, entitles him fully to disapprove of what he thinks might possibly have a detrimental influence on the fate of the Naples establishment. With regard to this apprehension I may be permitted to state that there is well founded hope that the Naples station will soon be free from such embarrassments as are the consequence of insufficient means, and that I always expected and desired a series of zoological stations to spring up which should not only follow but even rival the original one started by myself. The sudden appearance of zoological stations on the Normandy coast, at Trieste, Sebastopol, the foundation of the late Anderson School of Natural History in the United States, the proposition to create two stations at Heligoland and Kiel, and another plan to erect a station on the White Sea, brought before the Association of Russian Naturalists in Warsaw, furnish indubitable proofs that my belief was well founded. It may be that too little circumspection has been used in founding or planning several of these institutions; nevertheless their great number and rapid augmentation justify me in giving to my establishment such dimensions and so distinct an international character as to carry it as far beyond competition as possible.

I hope to be able to enter more fully into the development of the Naples station in the Second Annual Report, which I think will be ready next spring. It will show that till now the station has not only not suffered from competition but has been increasing very considerably the range of its activity and influence on the progress of biology.

Berlin, November 5

The Deep-sea Manganiferous Muds

IN the very interesting Address delivered by Sir C. Wyville Thomson, at Glasgow, on the *Challenger* expedition, while referring to the "red clay" deposit so general over the deepest parts of the Atlantic and North Pacific, the remarkable fact is mentioned that the clay contains numerous nodules of peroxide of manganese, which in some places are found in great quantity.[1] The Address goes on to say :—"This is a phenomenon which we are as yet unable to explain, and I do not know that there is any analogous instance in any of the older formations" (NATURE, vol. xiv., p. 494).

It is possible that this can be accounted for in the same manner as the formation of the "red clay" itself, assuming that the explanation given by Sir C. Wyville Thomson is the correct one, as there can be but little reason to doubt. It is true that exception has been taken to it by Dr. Carpenter, who considers the "red clay" to be "a *post-mortem* deposit in the chambers of the foraminifera."[2] It does not clearly appear, however, where such a *post-mortem* pseudomorphic deposit could come from in this case, while, were that opinion correct, then the *Globigerina* ooze itself ought also to form a pseudomorphic deposit of the same kind.

---

[1] See also "Report to Hydrographer of the Admiralty on the Cruise of H.M.S. *Challenger*." Prof. Wyville Thomson, F.R.S., *Proc.* Roy. Soc., vol. xxiv., p. 39.

[2] "Remarks on Prof. Wyville Thomson's Preliminary Notes on the Nature of the Sea-bottom," &c. *Proc.* Roy. Soc., vol. xxiii., p. 244.

Accepting, then, Sir Wyville Thomson's theory, the manganiferous deposit might be accounted for as follows :—

Manganese occurs in sea-water in very small quantities, sufficient, nevertheless, for detection. Forchammer has detected it together with iron and silica ; as also have Figuer and Mialhe.[1] It is, besides, almost invariably found in the waters of some springs, according to Prof. T. Sterry Hunt,[2] and spring-water sooner or later finds its way to the ocean. Again, it is found in the ashes of plants,[3] and it is therefore not unlikely that it may be secreted by other organisms, such as foraminifera, molluscs, &c.—in fact, Bischof found in the outer scale of oyster-shells 0·61 per cent. of ferric oxide, with some oxide of manganese[4]—and as its carbonate is isomorphous with that of lime and iron, it is perfectly probable that these should be found associated together, as indeed they usually are. Supposing, then, *Globigerina* shells to consist of carbonate of lime, with small traces of carbonate of iron, carbonate of manganese, peroxide of iron, and silicate of alumina, the following changes might take place while the shell was passing through water charged with carbonic acid gas and oxygen.

All the carbonates would first be dissolved. Then the carbonates of iron and manganese would be oxidised, as they readily part with carbonic acid in presence of oxygen, and the liberated carbonic acid would, no doubt, act on a fresh portion of the mixed carbonates. The silicate of alumina and peroxide of iron already in the shell[5] would not be affected. Thus there would be a continual deposition of silicate of alumina, peroxide of iron, and peroxide of manganese, very likely both hydrated. It is taken for granted here that the red clay is merely a silicate of alumina coloured by peroxide of iron, and not a double silicate of iron and alumina. It does not seem quite clear which is really meant in any of the reports. Alumina is found in small traces in river- and sea-water, perhaps in many cases as the silicate, which is soluble in minute proportions. Or it might originally exist as sulphate, in that state enter into the structure of marine organisms, and subsequently undergo alteration to silicate. Alumina has been found in small quantities in plants, but how combined is not yet known.

I believe the principal deposits of manganese ores are found in connection with limestone or dolomitic rocks, probably for the most part originally disseminated through them in small proportions, and subsequently concentrated in particular localities by the action of infiltrating water, and the nearest approach to the phenomenon described by Sir Wyville Thomson appears to be met with in the associated limestone, dolomite, iron ore, and nodular manganese ore of the Lahn district, as recorded by Bischof.[6] At the place where the iron and manganese beds are worked, there are several clay beds, varying from a few feet to several fathoms in thickness. These Bischof considers are the result of the continuous action of water containing carbonic acid, the argillaceous limestone being converted into clay. The manganese and iron ores lie beneath the clay beds, and it is most likely that these minerals were extracted from the argillaceous limestone at the same time as the carbonate of lime, having doubtless existed in small quantities as carbonates in the organisms forming the mass. In fact the lower clay beds still contain some manganese. There is thus considerable analogy between the two cases, the difference being that these old limestones having been formed in mass, in not very deep water, were not liable to be dissolved—immediately on the death of the organisms whose skeletons they were—by the action of sea-water, that part being played ages afterwards by atmospheric water. The result has been mainly the same, however, viz., the production of clay from the limestone, together with nodular manganese. Possibly had the corals, &c., forming that limestone had the opportunity of falling slowly, and each isolated, through a sufficient depth of sea-water, the result would have been a manganiferous mud, similar to these deep-sea clays.

As to the nodular structure of the manganese oxide, it is of course referable to the same mysterious molecular attraction which determines the segregation of all the carbonate of iron in the case of clay-ironstone in fire-clays and shales, and silica, as in chalk flints.

Since the above was written, the last number of the *Proceedings* of the Royal Society (vol. xxiv. No. 170), with Preliminary Reports on the Cruise of the *Challenger*, by Sir C. Wyville Thomson and colleagues, has come to hand. These reports contain a full description of the manganiferous muds, but no theory as to the origin of the manganese is as yet put forward.

[4] *Op. cit.*, vol. i., p. 198.

[5] It may be that there is a trace of uncombined ferric oxide already in these shells, since the *Globigerina* ooze, when treated with very dilute acid, leaves a red sediment like the "red clay" (see "The Cruise of the *Challenger*," NATURE, vol. xiv. p. 96). Sir Wyville hesitates to claim for the silicate of alumina and peroxide of iron that they exist in that form in the shells, rather supposing them to be products of alteration. But the latter is certainly found in some shells and in red corals It has been shown by Prof. A. H. Church that the red chalk of Hunstanton, treated with very weak acid, yields a residue closely resembling the deep-sea "red clay."—*Chem. News*, xxxi. p. 199.

Mr. Wallace on the Distribution of Passerine Birds

IN Mr. Wallace's recently-published work on Geographical Distribution, in more than one place the results arrived at from an inspection of his elaborate tables of genera and families do not agree with the numbers he uses in considering the general bearing of the facts adduced. Thus in his "General Remarks on the Distribution of the Passeres," vol. ii. pp. 299-302, he says (*l.c.* p. 300) : "The families that are confined to single regions are not very numerous, except in the case of the Neotropical region, which has *five*, the Australian has only *three*, the Oriental one, Ethiopian one, and the other regions have no peculiar families." Adopting his tables of the families of the Passeres, I find the numbers should be really as follows :—

Neotropical	7	...	Fams.	Nos.	39ª, 40, 41, 42, 44, 45, 46.
Australian	5	...	,,	,,	21, 22, 25, 49, 50.
Oriental	3	...	,,	,,	11, 12, 43.

The Nearctic region should also be mentioned as possessing one peculiar family, *i.e.* Chamæidæ. The statement that none of the turdoid Passerine families are exclusively American must also be modified to meet this fact. There are three families (*i.e.* Paictidæ, Pittidæ, Eurylæmidæ), instead of *two*, of the Formicaroid Passeres in the Old World, of which the Pittidæ can hardly be said to have only a "very restricted distribution."

The Australian genus Struthidea, of doubtful position, seems omitted altogether. W. A. FORBES

Cambridge, Oct. 30

Antedon Rosaceus (Comatula rosacea)

THERE are one or two rather hasty conclusions in the letters you have recently published upon the feather-star, which I will take the liberty of pointing out. My friend, Major Lang, arguing from his experience in Torbay, says : "It is evident that the habitat of Comatula is strictly defined, viz., in comparatively deep water, and amongst rocks." Last year, however, I took it in Salcombe Estuary, in shallow water, and not among rocks, but among the *Zostera marina*, to which numbers of the young stalked form were sticking. The well-known marine zoologist, Mr. Hincks, tells me that he took both the adult and stalked forms in great abundance in the same locality more than twenty years ago.

The President of the Birmingham Natural History and Microscopical Society, in commenting upon Major Lang's letter and other notices of the capture of the feather-star, says, "It is a most remarkable circumstance, therefore, that in the space of about three years, the species should have become numerous to the extent alluded to by Major Lang, more than a hundred being taken in one haul of the dredge." But this rapid increase in the numbers of the species since 1873 is imaginary, for dredgings in the two previous years had yielded the adult form by bucketsful from the neighbourhood of the Thatcher Rock.

In regard to the name, one can only wish for a scientific dictator to restore Lamarck's happily appropriate designation *Comatula*, in place of the earlier name, Antedon, the meaning and pronunciation of which are alike difficult to determine. It would be interesting to learn from political economists, in what category of labour, productive or unproductive, those investigations should be reckoned, which end in displacing some name universally received and understood in favour of one forgotten and obsolete. Justice to the ancient observer is pleaded as a chief reason for these revivals. But it is a poor renown to have helped to increase the ever-growing burden of scientific nomenclature.

Torquay, Nov. 6 THOMAS R. R. STEBBING

If you can afford the space I shall be glad to add a few words to the recent communications of Major Lang and Mr. Hughes to NATURE on the occurrence of *Antedon rosaceus* in Torbay.

I do not think *Antedon* has been more abundant than usual during the present year in this locality. An entry in an old note-book reminds me that a chance haul near the Thatcher Rock on July 11, 1871, brought up "plenty of feather stars," and since then during the six years I have dredged in Torbay, *Antedon* has been a very ordinary capture whilst dredging for other objects of interest.

The haul under Berry Head on July 25, alluded to by Major Lang, was undoubtedly an unusually prolific one, but had it not been for the fortunate discovery by Major Lang of the pedunculate form, the mere occurrence of an abundance of the adult feather stars would have made no impression on my mind and no notice would have been taken of it.

Remembering that the Birmingham Natural History Society had taken the young, I mentioned the fact to Major Lang, adding that I had never seen them myself. Next morning I was gratified to hear that on examining at his leisure the proceeds of the haul he had found them in quantity.

This successful result induced me to revisit the spot near the Thatcher after an interval of six years, and there, as I fully expected, *Antedon*, both adult and immature, was abundant. With this experience to guide me, I have since tried a third locality, when, though the adults were less numerous, the pedunculate young, and every stage of growth up to about an inch in diameter, appeared to me to be even more numerous than at Berry Head or the Thatcher.

In conclusion, I beg to say that it will give me pleasure to afford the fullest information in my power to any naturalist desirous of dredging in Torbay. It has often been a source of regret to me to see strangers wasting their time in dredging in spots where, as my old boatman used to say, they could not expect to meet with anything "of any consequence."

ARTHUR ROOPE HUNT

Southwood, Torquay, November 6

As the localities of *Antedon rosaceus* seem to be exciting interest, I may notice that I dredged the adult state in June, 1875, in Bressay Sound, sheltered in about 10 fathoms water, and in June, 1876, abundantly between Mount St. Edgecumbe and Duke Island, Plymouth, in about the same depth of water, in each case on a rocky bottom.

PHILIP B. MASON

Burton-on-Trent, November 8

Meteor

ON November 6 I observed a large meteor of a red colour. It commenced near the zenith and took a sinuous course about west-south-west, dividing into two portions after it had travelled about 40°, one portion disappearing about 10° above the horizon nearly due west, the other taking a north-west direction, and disappearing somewhat higher; it was not very bright, but seemed to be a large one. I should like to hear if anyone else has seen it; the time was between 8 and 9 P.M.

Clithero, Lancashire

T. NOSTRO

THE MUSICAL ASSOCIATION[1]

THE third annual session of this Society opened on Monday, November 6, with a paper of considerable interest from Alexander J. Ellis, Esq., F.R.S., "On the Sensitiveness of the Human Ear for Pitch and Change of Pitch of Notes in Music."

It appears from the Annual Report, just issued, that the Association numbers 170 members, and is in a sound financial position. It may therefore be considered to have passed its period of infancy, and should now be permanently reckoned among the learned confederations of the metropolis.

It is not altogether uninteresting to look back at its origin and to point out the fulfilment of the especial objects for which it was established.

The first conception appears to have emanated from Mr. William Spottiswoode, Dr. Stainer, and a few other gentlemen, representing about equally the scientific and artistic sides of music, who circulated a letter among their friends, and in a private meeting held at the house of the Treasurer of the Royal Society, laid the foundations of its future organisation. The original title chosen for the new society explained at more length its peculiar objects than that which it now bears; it was "Society for the Investigation and Discussion of Subjects connected with the Art and Science of Music."

The double function herein indicated has hitherto been steadily and rigorously carried out. Indeed the Council for 1876-7, numbering among its members eminent musicians such as the two professors of Oxford and Cambridge, Messrs. Hullah, Osborne, Goldschmidt, and Dr. Stainer, is supplemented on the side of Science and Literature by the familiar names of Mr. Spottiswoode, Prof. Tyndall, Dr. Pole, Mr. W. Chappell, and Mr. George Grove.

The contributions recorded in the two annual volumes of "Proceedings" are strictly in concordance with the initial programme; they cannot be better summed up than in the words of Mr. Spottiswoode's letter above-named, advocating "the formation of a society similar in the main features of its organisation to existing learned societies. Its periodical meetings might be devoted partly to the reading of papers upon the history, the principles, and the criticism of music, partly to the illustration of such papers by actual performance, and partly to the exhibition and discussion of experiments relating to theory and construction of musical instruments, or to the principles and combination of musical sounds."

In the first year Mr. Hullah, Dr. Stainer, and Mr. Sedley Taylor, spoke on musical notation and nomenclature; Mr. Bosanquet and Mr. Ellis furnished valuable illustrations of true and tempered intonation; Mr. Charles E. Stephens criticised Dr. Day's theory of harmony; Mr. Baillie Hamilton and the writer described their respective improvements in musical instruments.

During the second session there were two papers of great value, mainly historical, from Sir F. Ouseley, "On the History of Ecclesiastical Music in Western Europe;" and from Prof. W. G. Adams "On Wheatstone's Musical Inventions," two "On Notation," by Dr. Pole and Prof. Monk; two mathematical and physiological, by Lord Rayleigh, "On Our Perception of the Direction of a Source of Sound," and Mr. Lennox Browne "On the Management of the Voice;" two mechanical and instrumental, by Mr. de Pontigny, "On Kettledrums," and by the writer "On Standards of Musical Pitch;" one critical, perhaps even polemical, by the active secretary of the Association, Mr. C. K. Salaman, "On Musical Criticism."

Several of the above communications, especially Mr. Bosanquet's two exhaustive papers "On Temperament," call for full analysis; but the general status and purpose of the Association itself are so far novel as to deserve preliminary attention. Music, of all æsthetical subjects, is that which is most deeply marked by its bisection into art and science; much of the art, little of the science is ancient; for Euclid, Pythagoras, and even Galileo carry us only a short distance into the laws of harmony. But it is peculiar to music that instruments accidentally invented, slowly improved, fabricated simply for performance, and intended solely to charm the ear, have at a later period furnished the tools and apparatus of scientific analysis. The violins of Gaspar di Salo and Straduiarius, have for centuries illustrated the laws of harmonic sounds, and even as early as the time of Tartini, furnished the *Terzo Suono*, which figures so boldly in modern acoustics.

As the instruments themselves fulfil a double purpose, so are their votaries divided into two very distinct classes, those namely of artists and theorists. The essential value of Mr. Spottiswoode's proposal lay in the appreciation of this schism, and of the means towards healing it. The artistic world of music, great as the individual acquirements of some members as executants may be, is essentially a world of handicraftsmen; practising indeed a very subtle art, but led entirely, according to Aristotle's definition, by rules, and not by laws.

---

[1] Report and Proceedings of the Musical Association for 1874-5 and 1875-6.

The function of the scientific man is to expand these technical rules of art into the conscious and explained laws of science. How nobly this duty has been performed by Chladni, by Savart, by Wheatstone, and above all by Helmholtz, few artists are aware; nor indeed has there been hitherto any easy mode for their obtaining such information. They have been somewhat in the habit of sneering at the theorist as a "mathematician;" nor is it very remarkable that the other party, like the Dublin fishwife whom O'Connell called a parallelopipedon, should retaliate with even more opprobrious epithets. Hence old threadbare jokes about "catgut-scraping," Lord Chesterfield's contempt of musicians, and the like, which culminate in the epigram on Handel and Buononcini. This century is beginning to recognise that varying styles of musical art are not a mere question of "Tweedledum and Tweedledee," and that the "fiddler," though in an utilitarian point of view unnecessary to the maintenance of life, is highly conducive to education and civilisation. If artists are to maintain the improved position of later years it must be by cordially fraternising with the man of science, for thus only can their art hope to acquire the dignity and generalisation which are the prerogatives of ἐπιστήμη.

It is to be noticed that this view of the case appears to have been taken by many of our best professional musicians; for the list of members which heads either volume of these "Proceedings" is far more remarkable for individual eminence of the names than for their multitude. It is to be hoped that such a conviction will continue to extend. The number of points in which music is conterminous with pure science is considerable, and is daily increasing. Music, moreover, is among the most powerful means we have for cultivating that delicacy of the senses on which all accurate observation depends. It has, as yet, been too apt to fall into the hands of a sect or clique, whose disposition is naturally exclusive, and whose objects have often been the reverse of elevated. But with the great advance which has of late years taken place in general musical knowledge throughout England, and by the fostering care of societies like the present there is ground for anticipation that the science of music may rise to the esteem and consideration as an educator and humaniser which it once held in the writings of Plato, and in the palmiest days of old Greek thought.

W. H. STONE

ON THE RESISTANCE OF THE AIR TO THE MOTION OF PROJECTILES

THE experiments made by Hutton to determine the resistance of the air to the motion of shot were carried out by firing small spherical balls into the receiver of a gun-pendulum. As little confidence could be felt in applying his results to the large service shot at present in use, on the formation of the Advanced Class of Royal Artillery Officers, Woolwich, in 1864, it was thought desirable that a systematic course of experiments should be made with *elongated* shot, and upon a much larger scale. Afterwards, similar experiments were made with *round* shot.

The method of experimenting pursued by Hutton appeared to have been carried to its useful limits, and although a large ballistic pendulum had been constructed for Government, it was practically useless. The chronograph used in the experiments above referred to was invented and constructed for that purpose by the Rev. F. Bashforth, at that time Professor of Applied Mathematics to the Advanced Class, and Official Referee to the Ordnance Select Committee. This instrument is now in the Loan Exhibition, South Kensington.

A complete collection of the "Reports on Experiments made with the Bashforth chronograph, 1865–1870" (marked 84, B, 1941), has been published by Government, at the nominal price of one shilling.[1] It will therefore be sufficient here to state that the first set of experiments was made to test the new chronograph, in which the velocity of the shot varied from about 1,150 f.s. to 1,060 f.s. The resistance of the air was found to vary as the *cube* of the velocity. The next experiments were made with *elongated* shot of equal diameters and different forms of head. The velocities here varied from 1,500 f.s. to 1,090 f.s., and the law of resistance still appeared to be the *cubic*. Lastly, a course of experiments was made with *elongated* and *spherical* projectiles (solid and hollow) of 3, 5, 7, and 9 inches in diameter. The velocities of the elongated shot varied from 800 f.s. to 1,750 f.s., and those of the spherical from 800 f.s. to 2,400 f.s. At a given velocity the resistance of the air varied as the square of the diameter. But when the coefficient of resistance was obtained by dividing the numbers expressing the resistances by the cube of the corresponding velocity, the result was not now constant through these great variations of velocity. This coefficient was found to increase rapidly from 900 f.s. up to 1,050 f.s., and from 1,100 f.s. to 1,300 f.s. it was nearly constant, and for higher velocities it gradually decreased with the increase of velocity. The published reports give a full account of every round fired. Unfortunately it has not hitherto been found possible to express the coefficient of resistance by a simple function of the velocity. Mr. Bashforth has made use of the cubic law in his treatise on the motion of projectiles (1873). The trajectory is divided into arcs, and each arc is supposed to be described, while the coefficient of resistance retains its mean value for that arc.

In a tract on the remaining velocities, &c., of several service shot (1871),[2] Mr. Bashforth stated:—"For ogival-headed elongated shot, the resistance of the air may be said to vary roughly as the *sixth* power of the velocity for velocities 900–1,100 f.s.; to vary as the *third* power for velocities, 1,100–1,350 f.s.; and to vary as the *second* power for velocities above 1,350 f.s."

General Mayevski, Professor of Ballistics to the Academy of Artillery, St. Petersburg, published a work on Ballistics in Russian, in 1870, at the expense of the State. A translation of the more interesting chapters of this work was published in French by the author, in 1872.[3] In the preface to the latter work he states that "Les résultats des expériences faites par M. Bashforth en Angleterre sur les projectiles oblongs ont été déduits des données insérées dans les *Proceedings of the Royal Artillery Institution, Woolwich*, 1868. Les expériences de St. Pétersbourg sur la résistance de l'air au mouvement des projectiles sphériques et oblongs ont été faites par nous en [illegible] et 1869, et leurs resultats sont pour la première fois publiés dans notre traité. Afin que les expressions de la résistance représentent, avec une approximation suffisante, les résultats de nos expériences et ceux des expériences anglaises, faites avec des appareils perfectionnés, et que ces expressions permettent en même temps une intégration facile, *quoique par approximation*, des équations différentielles du mouvement, nous avons admis *pour les projectiles sphériques*, dans les limites des vitesses de 530$^{\text{ms}}$ à 376$^{\text{ms}}$ (1739-1230 f.s.) la résistance de l'air propostionelle au carré de la vitesse, et nous avons exprimé, à partir de la vitesse de 376$^{\text{ms}}$ (1230 f.s.) jusqu'aux petites vitesses, la résistance de l'air par un binome dont le premier terme est proportionel à la deuxième puissance de la vitesse, et le second à la quatrième [illegible] de la vitesse; *pour les projectiles oblongs*, quand leur axe de figure coïncide avec la direction du mouvement, nous avons admis, dans les limites des vitesses de 510^{ms} à 360^{ms} (1673-1180 f.s.) la résistance de l'air proportionelle au *carré* de la vitesse ; dans les limites des vitesses de 360^{ms} à 280^{ms} (1180-920 f.s.) nous l'avons admise proportionelle à la *sixième* puissance de la vitesse, et nous avons exprimé, à partir de la vitesse de 280^{ms} (920 f.s.) jusqu'aux petites vitesses, la résistance de l'air par un binome dont le premier terme est proportionel à la deuxième puissance de la vitesse et le second à la quatrième puissance de la vitesse," &c. (pp. vi., vii.). So that Mr. Bashforth employs one single law, the *cubic*, and makes his coefficient vary to suit the velocity, while General Mayevski varies his law of resistance according to the velocity. But in neither case does the law of resistance admit of direct integration. Mr. Bashforth supplies this defect by extensive tables calculated by quadratures, and ranting the cubic law, the results are exact. General integrations are approximations, and require bles also. But there is no dispute as to the of resistance encountered by elongated shot in g through the air. For General Mayevski observes: "Aussi pour compléter les données se rapportant aux projectiles de forts calibres, nous avons profité des tableaux des vitesses décroissantes déduites par M. Bashforth de ses expériences faites en 1868 au moyen de son chronographe ; ces tableaux comprennent les vitesses de 518^{ms} à 283^{ms} (1700-930 f.s.), qui correspondent aux trajets de 305 en 305 mètres des projectiles oblongs de 178^{mm}, 203^{mm}, et 229^{mm} (7, 8, and 9 inches), et qui sont obtenues pour le cas où le mouvement des projectiles peut être considéré comme rectiligne. Nous avons calculé d'après les résultats insérés dans ces tableaux les valeurs de la résistance correspondantes à différentes vitesses" (p. 38).

It ought to be stated that Hutton's results for spherical shot are very good indeed for velocities above 1200 f.s., while Didion's results, intended to correct Hutton's, were not quite so good. They both failed for lower velocities. It would be interesting to have the resistance of the air to projectiles determined for velocities below 900 f.s. But very considerable difficulties would be met with if the experiments were conducted in the usual manner, for the chronograph is most effective when there is a rapid variation of velocity. In the middle of the range the screens would have to be raised to a considerable height. It would be found difficult to fire shots through them all. If the shot were fired at low initial velocities from the ordinary rifled gun, there might be considerable doubts the steadiness of the shot.

e must be made to the collection of scientific memoirs on ballistics by the Comte de St. Robert published in 1872,[1] although they do not supply any new experimental data.

As it is found impossible to integrate the equations of motion of shot for the simple laws of resistance, of square cube, &c., it appears almost hopeless to search for an expression of the complicated law now known to hold good through a considerable range of velocities. These results would serve as tests of any theory of the resistance of the air; and if any theoretical investigations did satisfy these conditions, then we should have an expression for the resistance of the air to the shot, but it is almost certain that it would be too complicated to be of practical use.

B.

A LOCAL MUSEUM

THE population of the parish of Morton, 1871, was 2,099—the chief village, Thornhill, containing about one half of the population of the parish. The parish is situated on both banks of the Nith in the North of Dumfriesshire, Scotland. Yet sparse as is the population, and remote from the great commercial centres as is the district, it is supplied with a museum which well might grace a place of far more wealth and consequence. The building was erected by Thomas B. Grierson, and the collections in the museum were formed by him. The Duke of Buccleuch granted the land on which to build, together with stone. The memorial stone was laid with masonic honours in June 1869. The building, which was from the design of a local architect, is an oblong, consisting of a ground floor and gallery. The gallery is very appropriately supported by six oaks, as brought from the forest, being among the last of the natural woods of Nithsdale.

The *débris* excavated for the foundation has been well utilised by forming a large mound in the surrounding garden, which is faced on all sides by an excellent collection of the minerals and curious stones of the district, and forms a suitable habitat for hardy plants. The garden contains a great variety of flowering plants, of shrubs, trees, and cryptogamous vegetation, and is laid out with considerable art. Large objects, which do not suffer waste by atmospheric causes, such as stone crosses and querns, are placed at intervals in the walks. Great prominence has been given in the collections inside the building to objects which illustrate the history of the country. These include some valuable relics belonging to the Covenanters of the seventeenth century, and to the poet Burns. The collections illustrative of the unpolished and polished stone-period are very valuable. Some beautifully wrought cells and stone-hammers have been yielded by this part of Nithsdale. The bronze and iron collections are very fair. Among the quadrupeds is a skull of the ancient ox which roamed wild less than a century ago in Drumlanrig Parks, and which belong to the same variety as those at Chillingham and Hamilton Palace, which are supposed to be the sole survivors of the ancient Caledonian Urus. Among fish there is an interesting collection, which was the gift of the late Mr. Shaw, illustrative of the natural history of the salmon, and which shows that animal in its various different stages. The late Mr. Shaw threw great light on the development of the salmon, and destroyed some popular delusions concerning it. He was a keeper in the district under the Duke of Buccleuch. The abnormal form of animals are very various, many opportunities having occurred to fill the cases devoted to these from the pastoral and agricultural district around. In the collection of fossils due prominence is given to those belonging to the strata of the south of Scotland, and the industrial departments contain specimens of the manufactures of the country. The museum is free to the public on Saturday, and open for a small sum during the week. School children are admitted along with their teachers gratuitously on application. The proprietor, Dr. Grierson, is most indefatigable in his attentions and explanations to all willing to learn from his collection of objects. The

[1] Turin: Vincent Bora.

number of persons who have been admitted for the first time since the museum was opened, July 1872, is about 4,000. There is a society in connection with the museum which meets monthly, having for its object original research. Papers have been contributed, amongst others, by Dr. Grierson, Dr. Sharp of the London Entomological Society, and Mr. Shaw, schoolmaster. Dr. Sharp gave an exhaustive account of the Colorado beetle, and Mr. Shaw illustrated, by means of large diagrams, Darwin, Lubbock, and Müller's discoveries on the fertilisation of flowers by insects.

J. SHAW

Tynron, Thornhill

THE AUSTRIAN ARCTIC EXPEDITION[1]

NO doubt most of our readers have some acquaintance with the story of the memorable Austro-Hungarian Arctic Expedition in the *Tegetthoff* under the leadership of Lieutenants Payer and Weyprecht. We have at various times since the return of the expedition, upwards of two years ago, given details of the adventures of the party and of the results obtained; in vol. x. p. 524, we published a map showing the geographical discoveries which had been made. In the work named below all who have heard anything of the expedition or who take an interest in Arctic exploration will be glad to have a complete history of its doings from the artistic and graphic pen of one of its commanders, Lieut. Payer. We venture to think that Payer's narrative is likely to take its place among the classics of Arctic exploration; the skill with which he has told the story of an expedition so full of strange and unexpected events, the enthusiasm and interest which mark every page, its pathos and humour, the value of the information it contains, and the attraction of its numerous illustrations, are sure to make it a permanent favourite with old and young, and constitute it an authority on Arctic matters generally.

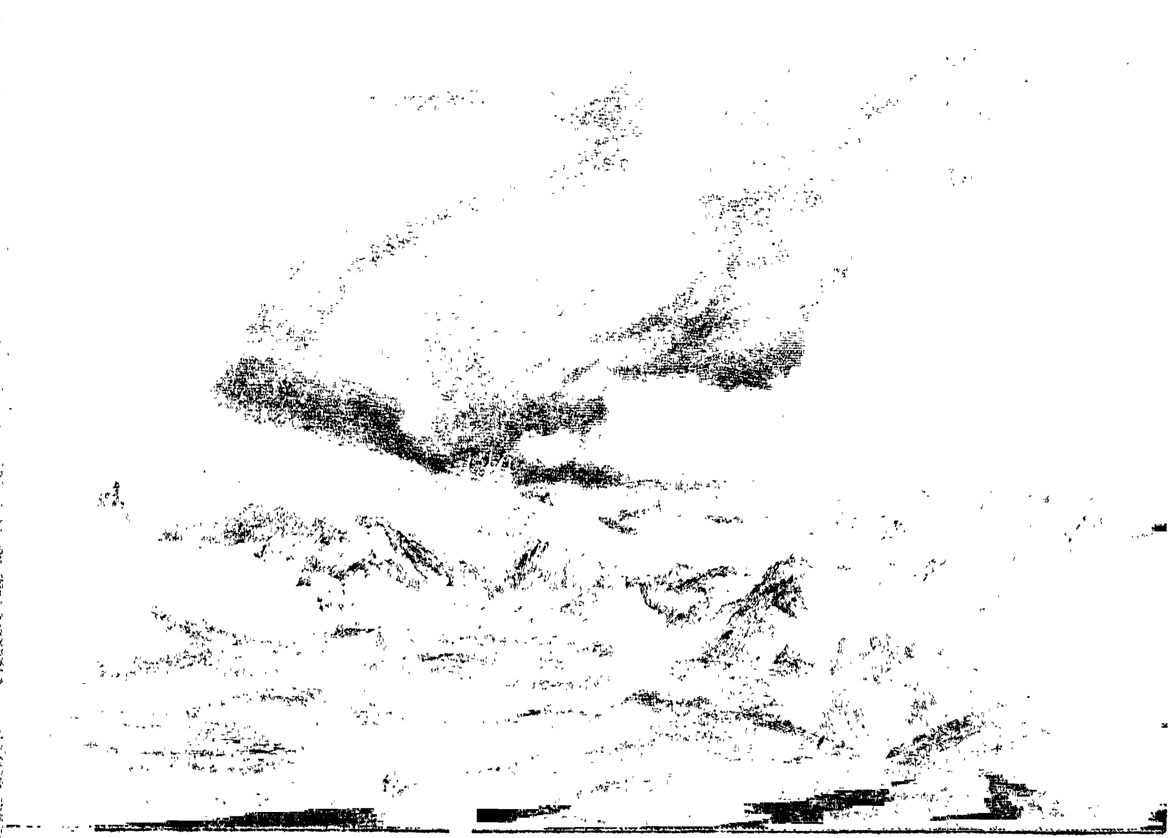
The Austrian Flag Planted at Cape Fligely.

The *Tegetthoff*, a screw steamer, expressly built for the purpose of this expedition, of 220 tons burden, fitted out for two years and a half, left Bremerhaven June 13, 1872, and Tromsoe about a month later, for the purpose of exploring the Arctic Seas in the Novaya Zemlya region. The vessel was equipped mainly at the expense of the Austrian Count Wilczek, and, including officers and men had only twenty-four souls on board. The ultimate destination of the expedition was not rigidly defined; they might make their exit by Behring Straits, or winter or the Siberian coast, or on any lands which they might be fortunate enough to discover. The first ice was met with in about 74° N., near the coast of Spitzbergen, and i remained with the ship more or less till the end. Only the year before, in a preliminary reconnaissance in a smal sailing vessel, the *Isbjörn*, by Count Wilczek, the se between Spitzbergen and Novaya Zemlya was found t be almost free of ice, and with a properly-equipped steam vessel there seemed to be no obstacle to pushing northwards indefinitely. In 1872 things wore a very differen aspect. The ice was entered in 74° N., and it require careful navigation to reach Cape Nassau, near which th *Tegetthoff* was overtaken by Count Wilczek in th

---

[1] "New Lands within the Arctic Circle. Narrative of the Discoveries of the Austrian Ship *Tegetthoff* in the Years 1872–1874." By Julius Payer, one of the Commanders of the Expedition. Maps and numerous Illustrations. Two vols. (London: Macmillan and Co., 1876.)

Isbjörn, who had thoughtfully followed to establish a depot for the exploring ship in the north of Novaya Zemlya. The two ships parted company on August 20, and a few hours after the *Tegetthoff* was beset by the ice in lat. 76° 22′ N., long. 63° 3′ E., and she never afterwards got out. Completely at the mercy of the moving ice-field, the ship drifted slowly in a general north-east direction during the winter, till somewhat north of 79° she turned westward in the middle of February, 1873. Though generally westward, the course was somewhat erratic. During the spring and summer of 1873, every effort was of course made to free the ship from her helpless position, in which apparently nothing could be done to carry out the object of the expedition. To be imprisoned thus for another winter appeared utterly intolerable, but all the efforts made failed, and by August everyone felt resigned to the inevitable. In August the ship took a turn towards the north, and on the 30th of that month the whole aspect of things suddenly brightened for the ice-bound explorers by the unmistakable sight of new lands. When in 79° 43′ N. and 59° 33′ E., new life was awakened in every breast by the sight of the mountains and glaciers of what is now known as Kaiser Franz-Josef's Land. Thus, then, when hope was lowest, the expedition drifted into success. It was too late that season to explore the new-found land, and it can easily be imagined how impatient all were for the advent of spring, to enable them to commence to gather the fruits of their lucky find. Lieut. Payer strongly advocates autumn as the best season for sledging, but as they could not run the risk of another winter in the ice, the sledge journeys were commenced early in March, and by the beginning of May Lieut. Payer had made three separate expeditions into Franz-Josef Land. In the first expedition, a short one, he explored Wilczek Island, the most southerly, and the south part of Hall Island. In the second journey he went right northwards, 160 miles, as far as he could go with sledges, to Cape Fligely, 82° 5′, making several subsidiary trips right and left of Austria Sound, on which he travelled, and which separates the two main divisions of Franz-Josef Land into Wilczek Land and Zichy Land. Finally a third short expedition was made to the north-west to M'Clintock Island, and on May 20, 1874, all necessary preparations having been made, the good ship *Tegetthoff* was abandoned. No other course was open to the commanders, if they did not want to run the risk of perishing along with their greatly enfeebled crew. By sledging and boating, a painful, wearisome, and slow progress southwards was made, so slow that in two months they were only nine miles from the ship, with a rapidly diminishing stock of provisions, though tobacco and water seem to have been the greatest wants; Payer says you could not have then done a man a greater favour than ask him to a pipe and a glass of water. Fortunately the open water was met with in about 78° N., and with little difficulty the wearied party rowed and sailed southwards along the west coast of Novaya Zemlya, until finally rescued, on August 24, by a Russian fishing-vessel at Cape Britwin. On September 3, all except poor Krisch, the engineer, who died of consumption and was buried on Wilczek Island, reached Vardö, not much the worse of their extraordinary experiences.



The Aurora during the Ice Pressure.

This bald outline of the course of the expedition can give one no idea of the intense interest which the detailed narrative assumes in the pages of Lieut. Payer. With the hand of a true artist, with pen and pencil, he sketches the life of the apparently forlorn party from day to day, with such clearness, and force, and sympathy that the reader becomes familiar with the peculiarities of each individual, and feels towards him in the end like an old acquaintance. The ways and characteristics of the very dogs, Jubinal and Sumbu and Pekel, and the rest, are sketched in a manner that would delight the heart of the author of "Rab and his Friends." While the work only pretends to be a general account of the expedition, it contains much of scientific value. Most of the scientific results yet remain to be published, though from time to time papers by Weyprecht, Höfer, and others appear in Petermann's *Mittheilungen*, containing elaborate discussions of the various scientific observations; we published some account also of the scientific results in three articles in NATURE, vol. xi. p. 366, *et seq.* Of Franz-Josef Land itself the author, by drawings, descriptions, and map, conveys a satisfactory idea. It is evidently an archipelago of about the size of Spitzbergen, stretching from about 80° to at least 83° N. lat., but how far from east to west is not ascertained. Running north and south, on each side of Austria Sound, are two main stretches of land, Wilczek and Zichy Lands, broken up, the latter especially, by many deep fiords, and with many islands in the channel between them. Payer got as far north as Cape Fligely, in 82° 5′ N., and from that saw land stretching northwards to 83°, Petermann Land, and another coast-line far to the west, King Oscar Land. The land, as might be expected, is a barren one, with mountains 2,000 to 5,000 feet high, and glaciers of such size, as argues that the country must have very considerable breadth. In many parts, and as far north as Payer went, animal life, bears and seals, and thousands of Arctic birds in great variety, abound; during the whole time of the expedition's sojourn fresh meat of some kind was seldom lacking. At Cape Fligely open water was met with, but it was only an extensive ice-hole or "polynia;" the idea of an "open Polar Sea" Lieut. Payer does not for one moment entertain. Distinct recent traces of foxes and even of hares were seen in some places, but no actual specimens were met with. Under the summer-sun, Lieut. Payer is of opinion, numerous streams will rush down the mountain sides, and some of the valleys be clothed with verdure. But for most of the year there is nothing but barrenness and ice and snow; the land is, of course, uninhabitable, and no trace of human beings was discovered. The islands are evidently volcanic, and reminded Lieut. Payer geologically of the rocks of North-east Greenland. Brown coal was found and coarse-grained dolerite abounds. But for details as to the appearance, the geology, the fauna, and flora, and other characteristics of Franz-Josef Land, we must refer the reader to the work itself. It would certainly be interesting to know more of this discovery, and perhaps means may yet be found to gratify a justifiable curiosity. The discovery of this group of islands greatly favours the theory of those who maintain that the Arctic basin is mainly an archipelago, and after all, our own expedition has found nothing that seriously weakens the theory.

From a scientific point of view the first chapter is probably one of the most important in the work. Lieut. Payer has evidently made a thorough study of ice in all its phases, both by means of direct observation (and both in the Novaya Zemlya seas and on East Greenland he has had ample opportunities for this) and by extensive reading of the works of previous explorers. In this first chapter are given the results of this investigation, the characteristics of ice of all kinds — field-ice, pack-ice, hummocks, icebergs, and other forms—in a more systematic and thorough manner than we remember to have seen before. Many popular delusions he demolishes, and writes with an accuracy and fulness that must be satisfactory to those who have had no opportunity of studying ice-forms for themselves. Icebergs, he tells us, with long, [illegible] like those exhibited in numerous illustrations, have no real existence. It is only fragments of field-ice, raised up by pressure, exposed to the action of waves and the process of evaporation, which are transformed into fantastic shapes. Icebergs are of a pyramidal or tabular shape, and in time they are usually rounded off into irregular cones. Altogether this chapter on ice is exceedingly instructive. The masses or thickness of floe-ice depends, he shows, not on age alone, but on several influences, pressure being one; so that the enormously thick ice met with by our own expedition does not need to be regarded as a remnant of the last glacial epoch, but due probably to unusual pressure, and the heaping of one mass upon another.

The year 1871, we have said, was in the Spitzbergen seas a great contrast to 1872, while 1874 again was as open as 1871. One of the most interesting, and in some ways instructive passages in the work, is where Lieut. Payer describes the fearful pressure to which the ship was subjected as she drifted northwards. For months these poor men had nightly to rush from their bunks on to deck ready to abandon the ship, which they expected to see every moment crushed to splinters. Payer's descriptions of the appearance and the agonising noises accompanying the ice-pressure are most impressive. The ice was comparatively smooth when first the ship entered it, but shortly the party were startled, when forced to rush on deck by the dreadful sounds which awakened them, by seeing the whole field crushed together, broken up, the pieces piled on the top of each other and lying at all sorts of angles, not unlike, indeed, the description given by Capt. Nares of the "Palæocrystic ice." Is not this, possibly, one more proof that the sea to the north of Robeson Channel was in an exceptional condition last spring? That we are almost entirely ignorant of the laws that regulate the movements of the ice in these regions is evident; no two successive years are alike, and the condition of one part cannot be inferred from that of another. In that very June, 1872, when the *Tegetthoff* was beset so far south on the Novaya Zemyla side, the *Polaris* pushed north with ease to 82° 16′ by the Smith Sound route, and could have gone further; and this year, when our own ships have had a life-and-death struggle with palæocrystic ice, whalers have been cruising and making easy discoveries between 81° and 82° N., on the Spitzbergen side. If any satisfactory results are to be obtained concerning these Arctic regions, is it not evident that the only means to obtain them is by the establishment of permanent stations all round? This is the conclusion to which Lieut. Weyprecht, one of the commanders of this expedition, has been driven. By the by, we would recommend Payer's description of the results of ice-pressure to geologists who desire to have a forcible illustration of the results of pressure in changing the configuration of a surface.

In these introductory chapters the author gives many valuable directions as to the equipment and conduct of Arctic expeditions, and, it may not be amiss to state, expresses his complete approval of M'Clintock's method of constructing and fitting sledges. We recently referred to the suggestion of the use that might be made of ballooning in Arctic exploration; Lieut. Payer thinks that valuable results might be obtained by means of a captive balloon. As to the Gulf Stream, he gives little ground for believing that it extends much beyond Spitzbergen; indeed he thinks that the wind was the main cause of the drift of the ship; though Baron von Wüllersdorf, who has discussed some of the results of the expedition, thinks it probable that there exists a sea-current in the seas between Novaya Zemlya and Franz-Josef Land; that at any rate its existence cannot positively be denied, although the prevailing winds may produce similar phenomena. He also thinks there is a great probability that the ocean stretches far to the north and east beyond the eastern end of Novaya Zemlya.

The crew of this expedition was a mixed one—German.

Sclavonic, Italian, Norwegian, and English being spoken, though all orders were given in Italian. It was well selected, and the ships equipped according to the most approved directions, but still scurvy broke out, though apparently not to so serious an extent as in the case of the *Alert* and *Discovery*. Fresh meat was abundant, and everything known to prevent or counteract the disease, but it broke out in both winters, the men improving during spring. Payer is distinctly of opinion that a judicious use of alcohol is a preventive, but evidently the real cause of this scourge of Arctic explorers has yet to be found out. The lowest temperature met with was a little over 40° R., though the general temperature was much milder. No one suffered seriously from frost bites, though they were common. The single death was due to consumption.

The conduct of the expedition by its two leaders, and the behaviour of officers and men, were all that could be wished. Observations in meteorology and magnetism, on the Aurora (of which there were many magnificent displays), geology, biology, and other departments of science were regularly and carefully made, and will no doubt gradually find their way into the general body of scientific knowledge and deductions. Unfortunately, many of the specimens, geological and zoological, had to be left behind with the ship. On the whole, this expedition is one of the most satisfactory in its conduct and results of all that have gone out to gather knowledge in these inhospitable regions, and Lieut. Payer has written its story in a style not surpassed in fascinating interest and scientific value by any of those old narratives that are still the delight of all who love to read of the adventures of daring men. The translator has had a hard task before him in putting the narrative into English dress, but he has succeeded, we think, completely; while retaining an unmistakable German flavour, the English version is thoroughly idiomatic and readable.

OUR ASTRONOMICAL COLUMN

THE NINEVEH SOLAR ECLIPSE OF B.C. 763.—In the Rev. A. H. Sayce's notice of the discoveries of the late Mr. George Smith amongst the Assyrian inscriptions in the British Museum (NATURE, vol. xiv. p. 421), reference is made to a solar eclipse in the month Sivan, which has been fixed to the year B.C. 763, June 15 (not in *May*, as printed in the notice quoted). The following are elements of this important eclipse—which has so direct a bearing upon the Assyrian chronology of the period—deduced upon the same system of calculation adopted for other ancient eclipses previously alluded to in this column:—

Greenwich Mean Time of Conjunction in R.A., B.C. 763, June 14, at 19h. 9m. 25s.

	°	′	″	
R.A.	73	9	43	
Moon's hourly motion in R.A.		39	56	
Sun's " " "		2	34	
Moon's declination	23	10	10	N.
Sun's "	22	53	4	N.
Moon's hourly motion in decl.		0	54	N.
Sun's " " "		0	17	N.
Moon's horizontal parallax		60	9	
Sun's " "		0	9	
Moon's true semi-diameter		16	24	
Sun's " "		15	25	

The sidereal time at Greenwich noon was 4h. 57m. 47s., and the equation of time 8m. 4s. additive to mean time. Hence the middle of the eclipse fell at 19h. 8m. 52s., and the following would be points in the line of central and total phase:—

	°	′			°	′	
Longitude ...	35	14	E.	Latitude ...	30	59	N.
" ...	40	2		" ...	32	58	
" ...	43	35	E.	" ...	34	19	N.

Sir George Airy places the Pyramid of Nimrud in long. 3° 20′ 8″ E., and lat. 36° 6′ 1″. Calculating directly for this point from the preceding elements we find a very large partial eclipse—

h. m.
Beginning June 15 at 7 52 A.M., local M.T.
Ending " " 10 23 " "

Greatest phase at 9h. 8m. A.M., magnitude of eclipse 0·987.

The breadth of the zone of totality in the longitude of Nimrud measured upon the meridian was 2° 5′, whence it appears that this point is distant by calculation about 50′ outside the northern limit, but at this remote period a very small alteration in the value of the moon's secular acceleration employed would suffice to bring Nimrud within the total eclipse, and it has been inferred that the eclipse was probably *total* at the station of the Assyrian Court, from the circumstance of the inscription referring to the phenomenon being underlined in the Assyrian Canon or register of annual archons at Nineveh, although there is no interruption in the official order of the Eponymes.

The discovery of the record of this eclipse was first announced by Sir Henry Rawlinson, in May, 1867.

THE COMET OF 1652.—This comet, which was observed for about three weeks only, is stated by Hevelius and Comiers to have equalled the moon in apparent magnitude, a fact pointing to a near approach to the earth. At present we have only the elements given by Halley in his "Synopsis Astronomiæ Cometicæ," which were calculated upon the observations of Hevelius, extending from December 20, 1652, to the 8th of the following month, published in the scarce volume of his "Machina Cœlestis." From this orbit the following positions and distances result:—

12h. G.M.T.		R.A. ° ′		Decl. ° ′		Distance from the Earth.
1652, Dec. 12	...	124 43	...	− 59 18	...	0·2275
16	...	96 19	...	43 42	...	0·1515
18	...	81 52	...	27 2	...	0·1308;
20	...	69 50	...	− 6 2	...	0·1314
1653, Jan. 8	...	33 28	...	+ 48 50	...	0·5627

So that the comet's least distance from the earth was about 0·13 of the earth's mean distance from the sun, and the real diameter of the cometic nebulosity rather less than 110,000 miles.

THE BRIGHTNESS OF JUPITER'S SATELLITES.—In connection with a recent reference in this column to M. Prosper Henry's direct comparison of the brightness of Jupiter's satellites with that of Uranus, it may be mentioned that Dr. Engelmann of Leipsic, in his memoir "Über die Helligkeitverhältnisse der Jupiterstrabanten," taking the star 132 Tauri as 5·3 in magnitude found the respective magnitudes of the satellites

I.	II.	III.	IV.
m. 5·52	m. 5·70	m. 5·32	m. 6·28

While a reduction of light-comparisons by Prof. Auwers between November, 1858, and May, 1860, gave

BIOLOGICAL NOTES

THE PROGRESS OF EMBRYOLOGY.—The value of Dr. Dohrn's Zoological Station at Naples has never been more conclusively demonstrated than by the publication, in a recent number (July, 1876) of the *Archiv für mikroskopische Anatomie*, of a series of researches by Dr. Bobretzky, of Kiew, on the development of certain forms of Gastropods. The systematic search for embryonic forms which is carried on under Dr. Dohrn's superintendence has enabled Dr. Bobretzky to publish a memoir of great value, illustrated by a hundred figures. His skill and success have been previously attested by his excellent researches on the development of the crustacean genera, Astacus, Palæmon, and Oniscus; and he has now passed with equal good fortune into the Gastropod group, dealing with the genera Nassa, Natica, and Fusus. These investigations are of special interest because, according to Prof. Ray Lankester, they are the first in which the method of cutting sections has been employed in the examination of these minute eggs and embryos. To have carried the conquests of embryology to such an extent is no slight achievement. Histologists are well aware that the estimate formed of structures by viewing them as transparent objects is liable to be erroneous, even in favourable circumstances; much more so when the objects have an appreciable thickness and are more or less opaque. In all cases it is desirable to obtain, if possible, confirmatory evidence by means of sections cut through hardened specimens; but the labour and manipulative skill required are much greater than in viewing bodies as transparent objects. At the same time Dr. Bobretzky's results convey an instructive warning to those who are tempted to generalise. Nothing is more common, or more detrimental, than for a series of generalisations to be founded on a new set of observations more or less limited in their range. By the continual discovery of fresh variations in the mode in which the ova of aquatic animals are segmented, and acquire their embryonic layers, it is to be hoped that students are being led to see that nothing but summaries of observed facts are of real value at present. Dr. Bobretzky seems to have made it evident that in the genus Nassa the three primary embryonic layers are all established during the segmentation of the ovum, and as a direct result of that process; and this is certainly a surprise. Again, a definite relation has been made out in certain cases between the orifice of the earliest invagination of cells and the permanent mouth of the animal. It is to be regretted, however, that Dr. Bobretzky throws doubt on Prof. Lankester's observations on some genera of fresh-water Gastropods, in which facts of a different character were discovered. However, the latter investigator has been stimulated to examine the development of the common *Paludina vivipara* anew, and has published an account of it in the *Quarterly Journal of Microscopical Science* for October last; his previous assertions appear to be very definitely confirmed, notwithstanding that the method of sections has not been adopted: the embryos, it may be stated, are amongst the most transparent in the Gastropod class. Although it must be a disappointment to ardent theorists to find that they are so far from a satisfactory goal, it may encourage young workers when it is seen that the field for independent investigation is practically unlimited, even in embryology. In invertebrates, at least, it appears that the development of every genus should be studied, and that new facts bearing on evolution, on the distribution of life, on the influence of external conditions, on the warping, so to speak, of the direct process of development by temporary influences acting during embryonic life, will reward all diligent work in this fruitful field.

NEW SPECIES OF ECHIDNA.—A very remarkable zoological discovery is announced from Genoa. Among the collections recently received by the Marquis G. Doria for the Museo Civico of that city from Mr. Bruyn, of Ternate, is a specimen of a new and large species of *Echidna* from the Arfak Mountains of New Guinea. As the only two Ornithodelphs hitherto known are exclusively confined to Australia, it is difficult to over-estimate the importance, as regards geographical zoology, of the existence of a third member of this peculiar group of mammals in the adjoining land of New Guinea.

SPHENODON GUENTHERI.—At a recent meeting of the Wellington Philosophical Society (New Zealand) Dr. Buller described a second species of Lizard (if Dr. Günther will allow us to call it so) of the genus *Sphenodon* (sive *Hatteria*). *Sphenodon guentheri*, as Dr. Buller proposes to designate this new form, "after the greatest of living herpetologists," is from the Brother Islands, whilst the original *S. punctatus* appear to be confined

A NEW FISH.—Dr. W. Peters has lately communicated to the Royal Academy of Science of Berlin the description of a new fish of the order *Leptocardii*. Of this most peculiar group of "Invertebrated Vertebrates," but one genus—the *Amphioxus branchiostoma*—has yet been recognised, though several more or less doubtful species of the genus from various parts of the world have been described. Dr. Peters has received from Australia several examples of a well-marked, though closely-allied, form, which he names *Epigomethys cultellus*, and which differs from *Branchiostoma* in having a high dorsal fin and in wanting the caudal and anal fins. These minute rarities were dredged up near Peale Island, in Moreton Bay, in eight fathoms water.

A NEW PERIPATUS.—A paper on *Peripatus*, by Capt. F. W. Hutton, Director of the Otago Museum, which will be found to be a valuable supplement to that by Mr. H. Moseley, in the *Transactions* of the Royal Society, has been published in the current number of the *Annals and Magazine of Natural History*. The author describes a new species, which he names *Peripatus novæ-Zealandiæ*, peculiar in being hermaphrodite. These strange animals, between 1 and 2 inches in length, are found in the West Indies, Chili, the Cape of Good Hope, and New Zealand. They have relations with worms and with the tracheate Articulata, and habits much like those of the woodlouse.

THE PERSIAN DEER.—In the same number of the same journal, Dr. N. Severtzoff has also an interesting communication on the affinities of the Persian Deer (*Cervus maral*), in which he shows that this species is identical with the Wapiti (*C. canadensis*) of Canada, that from the warmer locality changing colour in the summer, that from the colder not doing so. The author very reasonably suggests that the name *C. wapiti* or *C. maral* would be preferable to *C. canadensis*, now the distribution of the species has been shown to be so general.

FISHES OF THE ARALO-CASPIO-EUXINE BASIN.—The results arrived at by Prof. Kessler, after many years' study of the fishes of the Aralo-Caspio-Euxine region (which includes these three interior seas with their affluents) are as follows:—The number of described species is about 280, out of which 80 are marine, 100 fresh-water, and 40 brackish water species; 20 inhabit various waters, and 40 are migratory. 150 species belong exclusively to the region, and 10 have spread out into neighbouring regions at comparatively recent times. Out of the 120 other species, about 25 have a wide range of distribution, about 80 have migrated into the Black Sea from the Mediterranean, and about 15 fresh-water species have penetrated into the Aralo-Caspio-Euxine region from the north. Out of the 160 species limited exclusively to this region, 45 were found in the Black Sea, 54 in the Caspian, and 26 in Lake Aral. There are but 6 species which inhabit simultaneously the three basins of the three interior seas, 4 species which are common to the Caspian and Aral basins, and 25 to those of the Black Sea and the Caspian. The most characteristic families of fishes in the region are the *Gobioideæ* and the *Acipenseridæ*, the former being represented by no less than 50 species, out of which 40 do not extend over other regions; the genus *Benthophilus* of this family, which numbers here six or seven species, has no representatives abroad; and the genus *Scaphirynchus*, represented in the Amu and Syr-darya by three species, is known to have but one more species inhabiting the Mississippi.

DEVELOPMENT OF THE MAMMA.—Among the important histological investigations which have appeared quite recently is one by Mr. C. Creighton, M.B., in the current number of the *Journal of Anatomy and Physiology*, on the development of the mamma, and of the mammary function, in which the view generally received that the mamma is a complex extension downwards of the ectoderm or surface of the skin, is combated in favour of the account originally given by Goodsir, that the essential secreting structure of the breast develops from a matrix tissue at numerous scattered centres, which are the same from which the surrounding fat originates, and that the ducts arise out of the same matrix tissue by direct aggregation of the embryonic cells along predetermined lines. It is shown that in neither genus of Monotremata does the mamma possess a duct-system, it simply being a follicular gland. In the Cetacea these follicles open into a median unbranched simple duct. In the Marsupials and all other animals the ducts are branched, which causes the organ to be racemose. It may be noted that it was during the prosecution of this investigation that Mr. Creighton was led to the correct determination of the nature of the coagulation-appearances found in mucous and other albuminous fluids.

NOTES

We regret to announce the death, at Stuttgart, on the 5th inst., of the celebrated traveller and zoologist, Theodor von Heuglin. He was only fifty-two years of age, having been born in 1824, at Hirschlanden, near Leonberg, in Suabia. Von Heuglin had received a comprehensive education and had well prepared himself for his greater travels, by numerous visits to different European countries and by wide study. In 1850 he made a protracted stay in Egypt in order to study oriental languages, manners, and customs. After some visits to the interior of Arabia as well as the east coast of the Red Sea, he became secretary to Dr. Reitz, the Austrian Consul at Khartoum, and in that capacity visited the Upper Nile districts and Abyssinia. When Dr. Reitz had succumbed to the climate, von Heuglin returned to Khartoum, and succeeded him in the consulate. As consul he visited the White Nile, and eventually returned to Germany in 1856. Here he published his excellent "Travels in North-East Africa" (Gotha: Justus Perthes, 1857), which had been preceded (in 1855) by his "Systematic Review of the Birds of Africa." He again paid a visit to the Red Sea, and in 1860 took the lead of the expedition which was to find Vogel's traces, proceeding from the east; Steudner, Kieselbach, Hansal, Schubert, and Munzinger were members of this expedition, which, although acquiring valuable information about the Gallas districts, failed in its principal object. In 1862 von Heuglin returned to Khartoum with Steudner, and in 1863 made a fresh attempt to trace the course of the White Nile. The results of these travels were published in Petermann's *Mittheilungen* (1860–64). His merits were particularly great in ornithology; his drawings are true to nature, his descriptions exact, detailed, and extremely attractive. Also in Arctic regions von Heuglin gave proof of great intelligence and courage; he was almost more successful as an Arctic explorer in 1870 and 1871 than as an African traveller. His work on northern landscapes and animals (published by Westermann, at Brunswick) is one of the most attractive and handsomest records of travels yet published, and is highly esteemed by all who are interested in Arctic exploits. His death was a sadly unexpected one, a slight cough developed into inflammation of the lungs, to which he succumbed in the course of a few days.

We deeply regret that we have to record the death of Mr. T. Heathcote G. Wyndham. Few among the younger men devoting their life to the pursuit of scientific knowledge and to the teaching of science have formed for themselves a higher ideal of the training a man of science should impose on himself before venturing on original work, or on giving instruction to others. As a commoner of Oriel he took a first class in natural science in 1866, was Burdett-Coutts Scholar in 1867, and was afterwards elected Fellow of Merton. He undertook at Merton the duty of a lecturer in natural science, and the thoughtful care he took in his teaching was not only gratefully spoken of by many of the undergraduates, but frequently referred to in conversation by those who knew him. The branch of natural science which seemed gradually to have presented itself more prominently to his mind for his own especial study was the chemical side of mineralogy. But although for years he fitted himself for this work in all ways he thought requisite, sparing no pains in acquiring collateral knowledge that might bear on his subject, and though he had done original research which many other men would from time to time have thrown off in isolated papers, he held back from appearing in print. A paper on Idocrase and Garnet and one on Vesuvius are, so far as we know, all he published. But there is a prospect that some of his work will be preserved, as in conjunction with Mr. Gurney he had in hand a small work on chemical mineralogy. Although he had not yet achieved work to make his name marked in the world of science, yet those who knew him lament the loss of a scholar and a gentleman, and the lament is in no way softened by the unhappy circumstances attending his death.

The published results of the exploration of Lake Titicaca by Messrs. Alexander Agassiz and S. W. Garman, has just reached us. The expedition was undertaken during the early months of last year. Mr. Agassiz writes on the hydrography of the lake, describing the peculiarly uniform temperature at all depths, the potability of the water, the scarcity of the fish—six species only—and its previous greater extent. Mr. J. A. Allen gives a list of the mammals and birds collected, with field-notes by Mr. Garman. Of mammals only ten species were obtained, none new, four being Llamas. Of birds sixty-nine species were collected, including a new *Falcinellus* (*ridgwayi*), and a Gallinule (*Gallinula garmani*) closely resembling *G. galeata*. It is noted that many of the species had been but a short time before obtained by Messrs. Bartlett, Whitely, Hauxwell, and Jelski, and described by Messrs. Sclater and Salvin, Cabanis and others. Mr. W. Faxon describes the Crustacea, all excepting a species of *Cypris*, belonging to one amphipodous genus *Allorchestes*, of which seven new fresh-water species are added to the one or two already known. Mr. Agassiz gives a valuable hydrographical map of the lake, and records the presence of corals closely allied to genera living in the West Indies at the height of 2,900 feet above the level of the sea.

Messrs. Churchill have just published a third edition of Mr. Sutton's "Systematic Handbook of Volumetric Analysis," in which the author has embodied "all such novelties and modifications as experiment have proved to be worthy of notice."

We have to announce with great regret the death of another martyr to science. In a letter, dated September 15, the Rev. S. McFarlane writes from Somerset, Cape York: "We have just heard of the massacre of Dr. James and his partner, a Swede, at Yule Island by the natives of New Guinea. They had gone in their large boat to the east side of Hall Sound to shoot birds of Paradise, when they were attacked by three canoes, and both white men were killed. The native crew managed to get away in the boat, and brought the sad news here." Dr. James was a young American who had been collecting objects of natural history in Yule Island and on the opposite shores of New Guinea. His first collections arrived in this country about a fortnight ago, having been sent over by his friend, Dr. Alfred Roberts, of Sydney, to whose liberality the expedition was greatly indebted. The excellent way in which the specimens are preserved and the careful notes given by the collector show that Dr. James was enthusiastic in his work, and it is melancholy to think that so promising a scientific career has been thus prematurely cut short. A description of the collection of birds formed by the late traveller will be given by Mr. Bowdler Sharpe at an early meeting of the Linnean Society, in continuation of the articles on the avifauna of New Guinea, commenced during the last session of the Society.

The Forty-seventh Session of the Royal Geographical Society was opened on Monday evening by the delivery of the presidential address by Sir Rutherford Alcock. He referred to the satisfactory state of the Society, which now numbers 3,199 members, and to the valuable work it had done since its foundation for the cause of geographical research. He also referred with complete satisfaction to the work accomplished by the Arctic expedition, the leaders of which had done the only thing that could have been done under the circumstances. Sir Rutherford then spoke of the work of Cameron in Africa, the *Challenger* Expedition, Russian Exploration, the Oriental Congress, and on various other topics. He referred to the fact that geography and exploration have now assumed a much more scientific aspect than ever they had before; no traveller can gain distinction by mere topographical detail and descriptive power; his exploration must be conducted on a thoroughly scientific basis. To spread a knowledge of this aspect of geography, lectures are to be given during the winter by General Strachey on the general subject of "Geography in its Scientific Aspect," Dr. Carpenter on "The Physical Geography of the Ocean," and Mr. Wallace on "The Influence of Geographical Conditions on the Comparative Antiquity of Continents, as indicated by the Distribution of Living and Extinct Animals." After the President's address, Sir R. Douglas Forsyth read a paper on "The Buried Cities of the Gobi Desert."

The Lords of the Admiralty have addressed a letter to the Commander-in-Chief at Portsmouth, in which they request Admiral Elliott to express to Capt. Nares their lordships' warm approval of the conduct of all engaged in the Arctic Expedition. While they deeply commiserate the sufferings of the officers and men, and deplore the loss of life, they cannot but feel that their bearing and conduct have been in all respects worthy of British seamen. Their lordships approve the sound judgment displayed by Capt. Nares in at once, on the return of his sledge parties, determining to endeavour to extricate the ships and return to England, and they observe that his skill and energy in carrying out this determination, ably seconded as he was by Capt. Stephenson, were of the highest order. Capt. Nares proudly records that to uphold British honour and Christian duty to the death was the pre-eminent determination of all under his command.

A special Arctic meeting will be held under the auspices of the Royal Geographical Society at St. James's Hall on December 12, when papers on the various results of the English Arctic Expedition will be read by Captains Nares, Markham, and Feilden.

American observatories have been very diligent in the search for the supposed "Intra-Mercurial Planet," no less than nine having given their whole time to the search on October 2, 3, 10, and 11, viz., those of Dartmouth College, Harvard College, Cincinnati, Glasgow (Mo.), Washington, Albany, the Coast Survey in San Francisco, Ann Arbor, and the Observatory of Dr. Peters, besides others that have made no report. It is exceedingly creditable to the United States that they contain so many observatories, many of them national ones, in which astronomical observations are so diligently pursued.

The Free Spanish University we referred to in vol. xiv. p. 132, has been opened in Madrid, under the name of Free Institution of Education, for Government will not allow the assumption of the title University. Only 1,000 guineas have been subscribed, many of the shareholders being well-known Englishmen, among them Prof. Tyndall. The Institution is held at present in one storey of a large house, and has already seventy-three students, besides eight or nine ladies; the fees are very low. We hope this attempt to establish a university where unrestricted instruction can be given, will prosper, and that the professors, all men of high standing, will soon be able to have a building of their own.

The library of the late Adolphe Brongniart is to be sold by auction in Paris on December 4, and following days. The classified catalogue, arranged by M. Deyrolle, occupies 240 pp. 8vo. Copies may be obtained through M. Deyrolle, 23, Rue de la Monnaie.

The *Kölnische Zeitung* of November 9 reports on a meeting of the Rhenish section of the German and Austrian Alpenverein, held at Cologne on November 4. It appears that the Verein, the head-quarters of which are at Frankfurt-on-the-Maine, consists of sixty sections and numbers over 6,000 members. During 1875 over 2,000*l.* were expended for the construction of huts and roads in the Alps, and the Verein now owns about twenty-four houses in different parts of the mountains; it has also appointed a special commission for the supervision of guides and huts. Altogether the Verein is thriving, and we may look for important scientific results from its labours.

It is stated that M. Gessi has discovered a large branch of the Nile, 200 yards wide, with a good current, diverging from the White Nile, 100 miles south of Duffle. It is stated by the natives that it runs in an unobstructed stream into the Nile again, and, if so, water communication may possibly be established between Lake Albert Nyanza and Khartoum. Col. Gordon has discovered a large lake fifty miles in length between Urondogam and Mrooli, a little north of Victoria Nyanza (in 1° N. lat.), from which issues the main branch of the Nile, called Victoria Nile, running from the Victoria to the Albert Lake, together with a branch river which must either join the Sobat river or the Asua river.

The Italian geographical journal, *Cosmos*, for October contains a continuation of the papers on New Guinea, which it has made a specialty. The present contribution consists of further letters from Dr. Beccari and extracts from the *Challenger* reports.

To the November number of Petermann's *Mittheilungen*, Lieut. Weyprecht contributes No. 7 of his "Bilder aus dem hohen Norden," under the title of "The Walrus-Hunter." He describes in a graphic and interesting manner the yearly quest of the walrus-fishers in the Spitzbergen Seas, which is becoming more and more difficult and dangerous on account of the increasing scarcity of the animal.

The Geographical Society of Paris has received news from the Brazza-Marche expedition, now exploring the Ogove, the large stream which falls into the South Atlantic in the French African settlement of Gaboon. It was discovered by the explorers that, after running north to the first degree of S. lat., the Ogoive turns abruptly southwards into quite unexplored regions. MM. Brazza and Marche had lost almost all their goods destined to conciliate the African tribes and to pay for their labour. But the Society sent to them a large number of small objects which will enable them to proceed towards the sources of the river. It is supposed that, owing to the immense volume of its water, it is an outlet for some of the large lakes of the yet untrodden region.

A telegram from Calcutta states that the district of Backergunge was ravaged by a cyclone on the 1st inst. Thousands of native houses were destroyed. The town of Dowlutkhan was submerged by a storm-wave, which swept away all the buildings of the place. Five thousand persons are believed to have perished. Backergunge is a British district in the Bengal presidency, near the mouth of the Ganges, lying between lat. 22° 2'—23° 13'., long. 89° 49'—91°, and has an area of about 3,794 square miles. A severe cyclone has also been experienced at Chittagong.

THE *Kölnische Zeitung* of November 11 reports on a disastrous gale and snowstorm which raged with terrific force in the neighbourhood of Stockholm on the 5th inst. Over fifty vessels stranded near Kalmar, and all railway lines to the south and to Norway were completely snowed up, and traffic upon them interrupted. The latter had not yet been resumed on the 8th inst.

A MAGNIFICENT bolide was observed on Sunday night, November 5, at nine o'clock, at Clerey (Aube), in France. Numerous sparks were visible and an explosion was heard, although very feeble, owing to the immense distance at which it had taken place.

THE French Minister of the Interior has authorised the Municipal Council of Lyons to dedicate a bust to Ampère, the inventor of electro-magnets. This memorial will be placed in the museum where are gathered the memorials of the illustrious men who were born in the city.

THE transit-room in which the Bischofsheim instrument is to be placed is being fitted up at the Paris Observatory. The work is almost finished. M. Leverrier has asked the Minister of Public Instruction to appoint an administrative commission in order to better regulate the part which the Observatory is to take in the 1878 Exhibition.

THE new number of the *Ibis*, now in the press, will conclude the third series and the eighteenth volume of this ornithological periodical, which has been carried on by the British Ornithologists' Union with the greatest energy since its institution as the organ of that body in 1859. A fourth series, under the joint editorship of Messrs. Salvin and Sclater, will be commenced next year.

COUNT T. SALVADORI, of the Royal Zoological Museum of Turin, is engaged on a general account of the birds of the Papuan and Molluccan Islands, based principally on the large collections recently formed by the Italian naturalists Beccari and D'Albertis in those countries. The work will be published, when completed, in the *Annals* of the Museo Civico di Storia Naturale of Genoa, to which institution the above-named collections have been transmitted.

ON Thursday and Friday last week the Haggerstone Entomological Society held its annual exhibition at its place of meeting, No. 10, Brownlow Street, Dalston. It was only in 1857 that a few working men interested in insect-collecting discussed, in West Wickham Wood, the desirability of an east-end club for mutual assistance. A club was formed and now numbers a hundred members. The subscription is but a penny a-week, but with this a reference library has been accumulated. The type cabinet for the collections consists of forty drawers, in which there are now some 15,000 specimens, and the library and collection together are insured for 200*l*. All through the year the society meets every Thursday, and many points of practical importance (some of them bearing on "the theory of evolution" put to the test by breeding) have been discussed. Among the ways in which members of the society have done valuable work may be mentioned the preservation of the avenue of elms in Victoria Park from insect ravages by a knowledge of exactly how to proceed in dealing with the foe. Although this and several such societies do not obtrude themselves on the scientific world, they still, besides exercising a good effect on the members, often do work of sterling value.

WE understand that it is proposed at University College to give a larger development than before to the practical work of students in connection with the classes of mathematics, physics, and engineering in their workroom especially adapted to the purpose, and placed under the direction of a special teacher, M. Paul Robin. Various models to illustrate the theorems of modern and higher geometry, of kinematics and mechanics, so difficult to understand theoretically,—such models as are so largely represented in the South Kensington Exhibition collection—will be made in a simple manner by the students themselves, side by side with their theoretical studies. The best models, and such as require more time and accuracy for their construction, will be preserved in a small educational collection. It would hardly be possible to insist too strongly on the usefulness, or rather on the absolute necessity of such work for the successful study of science. It is only when the student has not only seen and handled various practical illustrations and applications of the theorems of geometry and mechanics he is studying, but when he has himself constructed them—however roughly approximate they may be—that the mathematical truths will be permanently impressed on his mind. Only thus can he become so familiar with them, that they will be a basis for acquiring further notions, and a source of further mental activity. We wish, therefore, complete success to this new enterprise of University College.

SHORTLY after the appearance of Prof. Tyndall's work on Glaciers, the Bologna Professor, Bianconi, observed that, while Tyndall's experiments certainly prove that rapid changes of form in ice are due to crushing and to regelation, they do not prove at all that ice is devoid of a small degree of plasticity, which degree might be sufficient to explain the plasticity of glaciers. He undertook, therefore, a series of experiments (described and published in 1871 in the *Mem.* of the Acad. of Bologna, 3rd ser. vol. i.) on planks and bars of ice submitted to bending and torsion. The bending of ice-planks having been afterwards the subject of researches of Messrs. Mathews, Moseley, Tyndall, and Heim, it will suffice to say that Prof. Bianconi, making his experiments at higher temperatures (from + 1° to + 5° Cels.), observed a still greater plasticity of the ice than that obtained by the experiments made in England and Germany at lower temperatures. These experiments proved that slow changes of form of the ice may go on without any crushing and regelation, and that ice enjoys a certain degree of plasticity notwithstanding its brittleness; the ice-plank can, indeed, be shattered to pieces, during its bending, by the slightest shock. Now, Prof. Bianconi gives in the *Journal de Physique* for October the results of his further experiments on ice, much like those of Heim, or, yet more, those of M. Tresca on the puncheoning of metals. Granite pebbles and iron plates are slowly pressed into ice at the same temperatures, and not only do they penetrate into it as they would penetrate into a fluid or semi-fluid, but also the particles of ice are laterally repulsed from beneath the intruding body, and form around it a rising fringe. Moreover, when a flat piece of iron is pressed into the ice, the fringe rising around it expands laterally upon the borders of the piece, and tends thus, as in fluids, to fill up the cavity made by the body driven in. These experiments tend thus greatly to illustrate the plasticity of ice; but it would be very desirable that M. Bianconi, if he continues his researches, should accompany them by some measurements (as has already been done by M. Heim) in order to obtain numerical values of the plasticity of ice under various circumstances.

AT the Warsaw meeting of Russian naturalists Prof. Mendeléeff described the results of researches he has pursued during 1875 and 1876 for the verification of Mariotte's law. His former researches had proved that the decrease of volume of the permanent gases proceeds at a slower rate than the increase of pressure exerted on them, if the pressure is less or much greater than the mean pressure of the atmosphere. The experiments of Regnault, made with air, nitrogen, &c., at pressures higher than that of the atmosphere proved, however, directly the contrary, and a series of measurements undertaken some years ago by Prof. Mendeléeff to verify those of Regnault, gave the same results. Suspecting that there might be some cause of error affecting in the same way both series of experiments, Prof. Mendeléeff and M. Bogussky constructed special apparatus eliminating all possible causes of errors and allowing the most perfect accuracy of measurements. With these they made a new series of researches, at pressures varying from 700 to 2,200 millimetres. These researches confirmed again the conclusions of Regnault, showing only numerical differences in the values obtained, and proving, for instance for the air, that its deviations from Mariotte's law are even less than appeared before. But the most important result of the researches is that the divergences from Mariotte's law shown by the air being negative at pressures above the mean atmosphere, as was observed by Regnault, proved to be positive (decrease of volume slower than the increase of pressure) at pressures below it. We must then conclude that the air experiences a change of compressibility at a certain pressure about the mean of that of the atmosphere; and this conclusion is supported by the circumstance that such a change was noticed also in the carbonic and sulphurous acid gases, but at pressures far lower than is the case for air. Only for hydrogen the divergence is of the positive kind at all pressures. Altogether we must conclude that the deviations from Mariotte's law are far more complicated than has been suspected.

AT the same meeting Prof. Czehovicz demonstrated the influence exercised by various sources of electricity on certain spectra, chlorine, oxide of carbon, &c. The inductive apparatus of Ruhmkorf gives a spectrum differing from that produced by the Holtz electric machine, not only by the number of rays, but also by their position and aspects. Prof. Czehovicz proposes therefore to make for comparative researches a selection of such rays as maintain the same aspect and occupy the same position whatever source of electricity be used; such lines will not be numerous.

AT the same meeting Prof. Grewingck presented the drawing of his geological map of the Baltic provinces, prepared for a second edition. It embodies the results of all acquisitions made in this department during the last fifteen years, and will soon be published.

THE Warsaw Zoological Museum having received during recent years valuable additions from America, Africa, and Eastern Siberia, presented by Count Branicky, is now very rich in the department of higher animals. It counts 514 species of mammalians, 3,216 of birds, and 400 of reptiles and amphibians.

THE Natural Science Club at Cambridge held several successful meetings during the two months' residence in the Long Vacation. The following papers were read:—"Hæckel's Gastræa Theory," by Mr. Marshall (St. John's); "Fermentation," by Mr. Stoddart (St. Peter's); "Some Salts of Chromium," by Mr. Houghton (St. John's); "The Relation between the Fore and Hind Limbs of Vertebrates," by Mr. Phillips (St. John's); "Growth," by Mr. Buxton (Trinity); "Theories of Heredity," by Mr. Sedgwick (Trinity); "Owen's Vertebrate Theory of the Skull," by Mr. Humphry (Trinity); many of which were followed by interesting discussions and remarks.

A GERMAN paper describes a dreadful fight between two Polar bears, male and female, in the Cologne Zoological Gardens. After a fierce struggle the female became exhausted, and was dragged by the male into the water basin in the den, and held down till life was quite extinct. He then pulled her out and dragged the body for a considerable time round the den.

FROM a correspondence in the *Times* we learn that the statue of Faraday, subscribed for years ago, and entrusted to Foley to execute, was left by that sculptor in the clay at his death. Since then, Mr. Burch, the principal pupil of Foley, has been entrusted with the founding and completion of the work.

THE second edition of Brehm's well-known "Thierleben" is about to be published in 100 parts, with entirely revised text and with almost entirely new illustrations taken from life.

AT the meeting of the Mathematical Society, on November 9, the changes were made which we intimated in vol. xiv. p. 581.

PART 5 of the second series of the great work, in quarto, upon the butterflies of America, with coloured drawings and descriptions, has just been published by Mr. Edwards, through Hurd and Houghton, New York, and sustains the reputation of its predecessors by the artistic elegance and superiority of its illustrations. These consist of five plates, executed by Miss Peart in her best style, giving, for the most part, not only the different sexes and varieties of the adult insects, but likewise the eggs, larvæ, and chryssalides, and the favourite plants upon which they feed. No new species are represented, although several of those included are of great rarity.

THE *City Press* states that some of the Livery Companies have a scheme in embryo for combining to form a College of Technical Instruction in a building to be erected on the Thames Embankment.

THE Board for superintending non-collegiate students give notice that an examination in physical science for the award of an exhibition of 50*l*. a year, granted by the Worshipful Company of Clothworkers, and tenable for three years by a non-collegiate student, will be held in the Censor's rooms, 31, Trumpington Street, Cambridge, commencing on Thursday morning, December 14, 1876, at 9 o'clock. Fuller information as to the subjects of examination and the conditions of tenure of the exhibition may be obtained from the Censor, Rev. R. B. Somerset, Cambridge.

A CAUCASIAN Society of Naturalists has been recently opened at Tiflis.

THE publishing house of Trübner in Strasburg are issuing translations of Macmillan's Science Primers, under the superintendence of the Professors of the University. There have already appeared Roscoe's Chemistry and Balfour Stewart's Physics, the former by Prof. Rose, and the latter by Prof. Warburg, Lockyer's Astronomy, by Prof. Winnecke, and Geikie's Physical Geography, by Prof. Oscar Schmidt, are in the press.

THE *Augsburger Allgemeine Zeitung* of November 5 gives some interesting details of the North-Dutch canal, which was opened officially by the King of Holland on the 1st inst., and which connects the city of Amsterdam directly with the German Ocean. It appears that the canal is 25 kilometres in length, that at its broadest part it measures 120 metres across its surface by 68 metres at its narrowest part. In the middle the depth averages 6 metres, but during the next two years the depth is to be made uniform all over the area of the canal, and to be increased to 8·20 metres, so that even the largest vessels can come close to the quays on both sides of the canal. Its name is to be Ymuiden, viz., mouth of the Y; at the spot where it reaches the sea two enormous moles or dykes have been constructed, reaching 1,600 metres into the sea, and forming a spacious port of refuge for ships during stormy weather; their extreme ends are no less than 1,200 metres apart. The total cost of the canal, which was borne by the Dutch Government as well as by the city of Amsterdam, amounted to more than twenty-six millions of florins, and it is expected that about seventeen millions more will be wanted for the construction of quays, warehouses, &c.; yet the undertaking cannot fail to be a success, owing to its incalculable importance with reference to the commerce of Amsterdam.

The following experiment has recently been employed by M. Merget to demonstrate the phenomena of gas-synthesis in plants: Two glass cylindrical vessels of 300 cc. capacity are placed with their open ends in a large vessel of water. The one is filled with hydrogen, the other with oxygen, their interiors are brought into communication by means of a branch which is long enough to reach from one end to the other. The level of the water is seen gradually to rise in each cylinder, and both gases finally disappear, without, however (as other experiments show), condensation or displacement being produced. At the beginning of the experiment there is nearly equality in the volumes which disappear, since a part of the oxygen serves to form carbonic acid; but in proportion as the water level rises in the two cylinders, and the projecting parts of the branch become shorter, the disappearing volume of hydrogen becomes more and more nearly double that of the oxygen. If a similar experiment be made with hydrogen and nitrogen in the two vessels, the disappearing volume of the gas is to that of the latter as three to one. Operating with hydrogen and carbonic oxide, both gases always disappear, but in very variable proportions. The most common was one volume hydrogen to one volume carbonic oxide, but the ratios of 4 : 1 and 5 : 1 were also sometimes met with. M. Merget finds in these variations the indication of a formation of hydrates of carbon, and of various carburets of hydrogen.

It is pretty generally supposed that crystallised nitroglycerine is considerably more sensitive to shocks and blows than the liquid substance, though there is nowhere evidence of this; and not only is practical experience against it, but from the theoretical standpoint it seems very improbable, for by reason of the positive melting heat of crystallised nitroglycerine, a considerable amount of heat must be employed to change its aggregate state before an explosion can occur. For decision of this question M. Beckerhinn (of the Vienna Academy) recently used a fall-machine furnished with a block of wrought iron 2·130 kilogrammes in weight, having at its lower end a hardened steel point of 7·068 sq. mm. A flat anvil of Bessemer steel was employed as support for the nitroglycerine, which was placed on it in a thin layer, and the weight dropped upon it from different heights. It was found that the mean height of fall with which explosion of the liquid occurred was 0·78 metres, whereas the frozen nitroglycerine did not explode till a fall-height of 2·13 m. was reached, showing that the frozen substance is considerably less sensitive to impact. M. Beckerhinn has determined some constants of the solid material. The average melting heat (from three experiments) appeared to be 33·54 heat-units. The density was found = 1·735 (the determinations were made at a temperature of + 10° C., which is near the melting-point of nitroglycerine); that of the liquid material was 1·599, whence it appears that in crystallising of nitroglycerine there is a contraction of about $\frac{10}{131}$ of the original volume.

Among the various works presented at the last Congress of Orientalists we notice a very useful catalogue, "Bibliographia Caucasica and Transcaucasica," by M. Miansaroff, the first volume of which recently appeared in St. Petersburg. It is the result of fifteen years' labour by the author and of careful research pursued by him in the chief libraries of Russia, Germany, Italy, and Turkey. The work is divided into three parts, devoted respectively to the Earth, to Man, and to the Mutual Influences of Nature and Man. The first two form the first volume (800 pages in 4to), which contains more than 5,000 titles of books and smaller papers on the Caucasus and Transcaucasus which have appeared in Europe and Asia since A.D. 1565. They are systematically arranged under the heads of geodesy, cartography, physical geography and geographical descriptions of localities, geology, botany and zoology, mineral springs, climate, medicine, &c. Whatever be the imperfections of this work, or of the classification adopted in it, it will nevertheless prove most useful for all engaged in the study of Caucasus.

Dr. King's report of the Royal Botanical Gardens, Calcutta, for the year 1875-76 has just reached us. In the acclimatisation of valuable economic plants in India, the Calcutta reports have become of late years the official record, and the present report by no means lacks interest on this score, though it is unsatisfactory to find that Dr. King's opinion is still against the possibility of either india-rubber or vanilla becoming staple products of Bengal. With regard to rubber plants both of the Para and Madagascar kinds, he says that during the year it has become more apparent than ever, that neither of these valuable plants can be grown for commercial purposes in the climate of Bengal. In the gardens as well as in the warm tropical valleys of the Sikkim Himalayas both kinds failed. Dr. King suggests that a suitable home may be found for them further north than Tenasserim, Ceylon, or perhaps Malabar. Vanilla, of which a number of plants were put out in the garden under shading similar to that used for protecting the pepper plants, has not made satisfactory growth, which it is suggested may have been due to over-shading, and a further experiment has been made by planting many of them under the shade of mango trees. The finest old vanilla plants in the garden are described as growing against a north wall; this year one of these plants was laden with pods, but an unusually high temperature caused these to drop prematurely. A better report is given of the ipecacuanha; numbers of plants have been sent from Calcutta to Ceylon, to the Neilgherries and to Burmah, and the quality of those grown in India is said to be equal to the best native Brazilian growth. A good deal of attention has been directed lately to the bamboo as a source of paper-making material, and it has been thought that it might be cultivated with profit in India for this special purpose, the young tender shoots being reduced to a rough kind of paper-stock for convenience for transmission to England. Dr. King points out that if the old stem would answer the purpose there is plenty of material in India, and a large revenue would accrue, but the young shoots are only produced at a certain season; nevertheless, experiments are being made with a view to utilise the bamboo for this purpose. In the distribution of plants and seeds, we learn that no less than 23,106 plants, and 6,343 parcels of seeds, were sent out during the year. It is satisfactory to know that amongst Dr. King's other multitudinous duties he has found time to prepare a "Manual of Cinchona Cultivation," and to edit other works on Indian botany. We also learn that Mr. Kurz's "Forest Flora of Burmah" is passing through the press.

Part 3 of vol. i. of the *Proceedings* of the West London Scientific Association has been published, and contains several interesting papers and accounts of excursions.

The October part of the *Journal* of the Franklin Institute contains an interesting history of the steam-engine in America.

Messrs. Williams and Norgate send us the following German scientific works:—"Bilder aus Aquarium," by Dr. Hess, of Hanover; and "Grundriss der Zoologie," by Dr. Gustav von Hayek.

The additions to the Zoological Society's Gardens during the past week include two Esquimaux dogs (*Canis familiaris*) from the Arctic region, presented by Capt. Allen Young, S.S. *Pandora*; four Viscachas (*Lagostomus trichodactylus*) from Buenos Ayres, presented by Mr. C. F. Woodgate; two Banded Ichneumons (*Herpestes fasciatus*) from West Africa, presented by Mr. W. N. Bakewell; three Chirping Squirrels (*Tamias striatus*) from North America, presented by Mr. F. W. Stockwell; a Peregrine Falcon (*Falco peregrinus*), European, presented by Mr. Chilton Newburn; a Green Monkey (*Cercopithecus callitrichus*) from West Africa, presented by Miss Ridsdan; three American Red Foxes (*Canis fulvus*), a Golden Eagle (*Aquila chrysaëtos*) from North America, six Clapperton's Francolins (*Francolinus clappertoni*) from West Africa, deposited.

SOCIETIES AND ACADEMIES

LONDON

Chemical Society, Nov. 2.—Prof. Abel, F.R.S., president, in the chair.—The President announced that the Goldsmith's Company had contributed 1,000*l*. to the recently-instituted research fund of the Society.—Mr. Lupton then read a paper on the oxides of potassium, after which communications were read on certain bismuth compounds (Part III.), by M. M. P. Muir.—On phospho- and arseno-cyanogen, by W. R. Hodgkinson.—A secondary oxidised product found during the reduction of stannic ethide to stannous ethide, by W. R. Hodgkinson and G. C. Matthews; and a preliminary notice on pigmentum nigrum, the black colouring matter contained in hair and feathers, by W. R. Hodgkinson and H. C. Sorby. This black colouring matter is left on digesting the coloured hair or feathers with dilute sulphuric acid, but is present only in very small quantity.

Zoological Society, November 7.—Prof. Newton, F.R.S., V.P., in the chair.—The Secretary read a report on the additions that had been made to the Society's Menagerie during the months of June, July, August, and September, 1876.—A letter was read from Dr. Otto Finsch, relating to the supposed existence of the Wild Camel (*Camelus bactrianus*) in Central Asia.—A letter was read from Mr. E. Pierson Ramsay, giving a description of the habits of some *Ceratodi* living in the Australian Museum, Sydney, which he had lately received from Queensland.—Mr. W. K. Parker read a memoir on the structure and development of the skull in the sharks and rays.—Prof. A. Newton made a correction of some of the statements in Canon Tristram's "Note on the Discovery of the Roebuck in Palestine." (P.Z.S., 1876, p. 421).—Lieutenant-Colonel Beddome gave the description of a new species of Indian Snake from Manantawaddy, in the Wynaad Hills, which he proposed to name *Platyplectrurus hewstoni*.—Dr. G. E. Dobson, communicated a monograph of the Bats of the group *Molossi*.—Dr. A. Gunther, F.R.S., read a report on some of the recent additions to the collection of mammalia in the British Museum, amongst the more remarkable of which was a new form of Porcupine, from Borneo, proposed to be called *Trichys lipura*, and a new Marmozet, obtained by Mr. T. K. Salmon, near Medellin, U.S. of Columbia, to which the name *Hapale leucopus* was given.

Royal Microscopical Society, Nov. 1.—H. C. Sorby, F.R.S., president, in the chair.—A paper by Dr. G. W. Royston Pigott on a new refractometer was read by the President and illustrated by drawings and by the instrument removed for the occasion from the Loan Collection at South Kensington.—A paper by the Rev. W. H. Dollinger, on experiments with sterile putrescible fluids exposed alternately to an optically pure atmosphere and to one charged with known organic germs, was read by the Secretary.—A paper by Mr. F. H. Wenham, on the measurement of the angle of aperture in object glasses, was read by Mr. Ingpen.

PARIS

Academy of Sciences, November 6.—Vice-Admiral Paris in the chair.—The following papers were read:—On an experiment which should be made with a view to the destruction of phylloxera, by M. Em. Blanchard. He advises a general adoption of the method of coating the vines and stakes in winter with coal tar, so as to destroy the eggs lodged in the fissures or under the bark.—Reply to M. Balbiani with regard to migration and egg-laying of phylloxera, by M. Lichtenstein. It is the nutriment and not the interior conformation of the insect that produces the fecundity. M. Lichtenstein does not accept the theory of degenerescence or exhaustion of the females.—Letter to M. Dumas on the products of the winter egg of *Phylloxera vastatrix*, by M. Boiteau.—M. Mouillefert presented some photographs showing the efficacy of treating phylloxerised vines with sulphocarbonate of potassium.—On the efficacy of iodides against saturnine intoxication, by M. Faure. He considers that a workman taking 5 to 10 centigrammes of iodide of iron or of potassium daily will have satisfactory results, and not be forced to interrupt his work.—On the results obtained by illumination of photographers' studios with violet light, by M. Scotellari. Violet light acts more rapidly than white or blue, and so requires shorter exposure. Some persons are very impressionable to ordinary light, but not to violet rays. The photographs got with violet rays are better modelled, and have a better finish.—M. Farret communicated results he has obtained in organisation of exercises for remedying Daltonism. These have been established in several schools, and he hopes to introduce them into the army and navy, railways, &c.—Researches on the production of electro-chemical deposits of aluminium, magnesium, cadmium, bismuth, antimony, and palladium, by M. Bertrand.—On a new dynamo-magnetic phenomenon, by MM. Trève and Durassier. A horseshoe magnet of any length is covered on one face with a varnish, or, better, a plate of glass. A cylinder of soft iron is laid on its neutral part. It commences to move towards the poles, and reaches them in a time which is naturally a function of the weight of the cylinder and of the coercitive force of the magnet. Thus the magnetic attraction is exerted over the whole extent of the magnet. A new mode is afforded of estimating the magnetic force by the mechanical work which it has effected. The product of the movable weight by the space traversed, divided by the time, will be the rigorous measure of this force. Determining the force, *e.g.*, for three large and three small magnets, identical in form and weight, containing respectively 0·250, 0·500, and 1 per cent. of carbon, the authors think it perhaps possible to define the unit of magnetic force, or *magnetie*, and to establish its equivalence in kilogrammetres. The phenomenon also helps them to determine the magnetic conductivity of steels in relation to their proportions of carbon.—Examination of wine for fuchsine, by M. Bouilhon. He employs hydrate of baryta in excess. It decomposes perfectly the salts of rosaniline, precipitates the colouring matter of the wine, and furnishes, by filtration, liquids of ambreous colour, which do not give persistent emulsions with ether.—Contributions to the anatomy and histology of the Echinida, by M. Fredericq. The nerves and muscles are described. The latter are formed of very thin cylindrical fibres, quite smooth and homogeneous throughout their length. Using various reagents, he could not detect the least trace of transversal striation. The fibres have a fibrillar structure, often with elongated nuclei applied on their surface, but they are without an enveloping membrane. They are birefringent, and are strongly impregnated with colouring matter and osmic acid. The muscles contract strongly under electric excitation, but not so suddenly as striated muscles.—Observation of a bolide, on the night of November 5, 1876, by M. Meunier. A fire-ball, the size of one's fist, was observed near α of Ursa Major; and behind, its trajectory south to north was traceable as a luminous line, commencing near Capella. The flash was bluish, and appeared brighter than moonlight.

FERRIER ON THE BRAIN

The Functions of the Brain. By David Ferrier, M.D., F.R.S. With numerous Illustrations. (London: Smith, Elder, and Co., 1876.)

I.

THIS is in many respects an important work. Full of experimental facts and theoretical suggestions, clearly and forcibly written, it is important as a contribution to our knowledge (and our ignorance) of the functions of the brain. The reader must not misunderstand my parenthesis as an epigram. That we are ignorant of brain-function is undoubted; and this ignorance is sustained and fortified by the "false persuasion of knowledge" which prevents search in other directions. Such false persuasion of knowledge will be deepened by Dr. Ferrier's work—all the more because of its merits, *if* the conclusions maintained there are erroneous, and the conceptions which determine them are unphysiological; and on both points I am inclined to judge affirmatively. There is something seductive in the precision of his statements and the unhesitating confidence with which only one side of a question is presented. The reader is easily led captive by a writer who has no hesitation. Add to this the many difficulties which stand in the way of controlling by experiment the experimental data, and the indisposition of most men to undertake the labour of verification, and we may foresee that physicians and psychologists will eagerly accept this work as an authoritative storehouse of material for their speculations. They will see how its "facts" harmonise with their own pet errors. They will interpret clinical observations or psychological facts by its conclusions. Already we have seen various theories invoking the Hitzig-Ferrier views; and when nerve-cells of a larger size than usual are found in a particular region of the cortex they are straightway declared to be motor-cells, because the region is said by Hitzig and Ferrier to be motor, while the existence of these cells is adduced in confirmation of the hypothesis respecting the region!

In view of the too-probable precipitation in adopting the conclusions of this work, we cannot do better than emphasize the warning with which the author closes his Introduction:—

> "We are still only on the threshold of the inquiry, and it may be questioned whether the time has even yet arrived for an attempt to explain the mechanism of the brain and its functions. To thoughtful minds the time may seem as far off as ever."

The volume opens with an elementary sketch of the structure of the brain and cord, followed by a short chapter on the reflex functions of the cord, with passing reference to Pflüger's view of its sensory functions, and to Goltz's experiments against that view. Then follows a chapter on the medulla oblongata as a respiratory and vaso-motor centre; and one on the general relations of the mesencephalon and the cerebellum. After full, yet brief accounts of what is taught respecting the effects of removing the cerebrum, the mechanism of equilibration, the muscular sense, the function of the semicircular canals, vertigo, co-ordination of locomotion, and finally the mechanism of emotional expression, we are brought to the main topic of the book—the functions of the cerebrum and basal ganglia. Let a word, in passing, be also given to the excellent chapter in which the psychological aspect of the cerebrum is treated.

Rich as the work is in facts and suggestions, it is so deficient in the indispensable correctives of counterfacts and arguments, that the reader must be cautioned against accepting any position unless elsewhere verified. Partly because, from long occupation with his subject, Dr. Ferrier has become unable to see it in any other light than that of his own hypothesis, and therefore doffs aside all counter-facts and counter-arguments as not really significant; partly, perhaps, because his memory has let slip what must have entered into his knowledge; from one cause or another there is a disregard of counter-evidence, which, in a second edition, I should seriously urge him to rectify. Let me cite examples.

In arguing against the sensory functions of the spinal cord, the experiment which he urges as decisive is Goltz's well-known experiment on the insensibility of the brainless frog to pain. I formerly (NATURE, vol. ix. p. 84 pointed out the defect in logic, which concludes from the fact that under certain conditions a brainless animal is insensible to pain (equally to be said of animals with brains), therefore it is altogether without sensibility. Pain and sensation are so far from being equivalent terms that not only are the great mass of our sensations without pain, but some cannot even be exaggerated into pain. Dr. Ferrier probably did not read the article in which I answered Goltz; but did he also overlook the article in the *Journal of Anatomy* for November, 1873, or the same article in the *Studies in the Physiological Laboratory of Cambridge*, Part 1, where Prof. Michael Foster showed by decisive experiments that the facts observed by Goltz had another interpretation? Again, is it possible that Dr. Ferrier has never been made to hesitate in assigning the optic thalami and corpora striata respectively as the integration of sensory and motor centres, by the observations and experiments which show that sensibility sometimes persists after total destruction of the optic thalami, and that paralysis does not always follow destruction of the corpora striata? One such observation would be decisive against these localisations. But Dr. Ferrier neither disproves the facts nor suffers them to disturb his views of the functions of these ganglia. Finally, there is an experiment by Dr. Burdon Sanderson which, as I shall presently show, cuts the very ground from under Dr. Ferrier's feet—yet this he does not even mention. He probably overlooked its significance; at any rate he leaves his readers without the advantage of knowing that there is such a fact.

That this disregard arises from no unfairness, but simply from the onesidedness which comes from preoccupation with certain views, is evident in the way he equally disregards his own counter-evidence. A notable instance is the first assigning the occipital lobes as centres of organic sensations on the faith of observed absence of such sensations when the lobes were removed, and then citing a case of complete recovery of such sensation five days afterwards, and instead of recognising this as decisive against his hypothesis, still persisting in maintaining it.

Thus much on what may be called the "personal equation." Another and more serious source of the misleading effects of the book seems to me its following the increasingly popular but thoroughly unphysiological conception of Localisation. Were not the current notions respecting organ and function very chaotic, and were not the indispensable artifice of analysis mistaken for more than an artifice which demanded rectification by synthesis, we should marvel to witness so many eminent investigators cheering each other on in the wild-goose chase of a function localised in a cerebral convolution. I will not, however, dwell on this point here, because it is one which would require a long discussion. It is only mentioned as a general *caveat*, and as leading up to the main question of cerebral excitation.

In 1870 Hitzig and Fritsch startled the scientific world by announcing that the universally accredited notion of the brain not being excitable was an error. The most eminent experimenters had declared that mechanical, chemical, and electrical stimuli were utterly powerless to excite the grey matter; and many a writer pointed to the paradox of the chief organ of sensation being *insensible*. We may here note another example of the common confusion of sensibility with pain; the brain was said to be "insensible" because no cutting, burning, pricking, or galvanising of it yielded evidence of pain; whether other evidence of sensibility might have been present was not asked. The utmost the experiments could prove was that the brain was not excitable by these abnormal means, though excitable by the very different normal means of peripheral stimulus. And even this conclusion Hitzig and Fritsch upset, by demonstrating that there were certain regions of the cortical substance which were excitable by electricity, as proved by the movements following such excitation; and the other "non-excitable regions" they inferred to be also excitable, though in another way, namely, by the production of sensations (*Vorstellungen*).

This was an epoch-making discovery. Experimenters in Germany, Italy, England, Switzerland, France, and America, quickly verified it, although differing among each other both as to the particular facts, and their interpretation. Among these followers the chief place must be assigned to Dr. Ferrier, both for the extent and the precision of his results; accordingly the names of Hitzig and Ferrier are usually coupled in speaking of the new hypothesis that various motor centres are located in particular spots of the cerebral cortex.

Although I have called it an epoch-making discovery, because I believe it will open a new track for the anatomical and physiological interpretation of the nervous mechanism, which will one day enable us to follow the whole pathway of stimulation, instead of—as at present—leaving us with the vague conception that "somehow" the cerebrum determines movements by setting the motor apparatus in action, I do not think that the hypothesis of motor centres in the cerebrum is tenable; nay, more, I *do not think that Hitzig and Ferrier have proved the grey substance to be excitable*. It is one thing to admit that the brain is excitable, another to admit that the excitation so effected is effected by calling into activity the special property of the grey substance. We do not consider the fauces to be the centre of vomiting, although tickling the fauces will be followed by retching. We do not consider the centre of laughter to be located in the sole of the foot, because tickling the sole causes laughter. Something more is needed; and it is precisely this something more which the Hitzig-Ferrier hypothesis has yet to find, namely, the anatomical connection of the so-called centre with the motor apparatus.

Has any proof been adduced that the electrical stimulus *first* acts on the cortex, and *then*—by the stimulation there produced—on the white substance, which in turn acts on the motor ganglia? *None that withstands criticism.* Knowing as we do that if the cortex be removed, or destroyed, the electrical stimulus nevertheless on reaching the white substance determines the same movements which had previously been determined when the stimulus was applied to the cortex, we may fairly ask: What proof is there that the current does not pass *through* the cortex (as through any other conducting medium) without exciting its activity? That it does simply pass through the cortex is probable on two grounds: (1) only the electrical current causes an excitation; mechanical and chemical stimuli have no such effects, because they cannot pass through the cortex to reach the white substance; (2) it is a well-known law that the propagation of neurility, *unlike* that of electricity, takes place only at insensible distances: if the nerve be divided, and the two cut surfaces be brought into the closest possible contact, there is still no propagation of the excitation from one surface to the other; whereas electricity passes freely *across* the cut surfaces. Now here Dr. Burdon Sanderson's decisive experiment, formerly referred to, comes, as I said, to cut the very ground from under the Hitzig-Ferrier hypothesis. "If that part of the surface of the hemisphere which comprises the active spots is severed from the deeper parts by a nearly horizontal incision made with a thin-bladed knife, and the instrument is at once withdrawn without dislocation of the severed part, and the excitation of the active spots thereupon repeated, *the result is the same as when the surface of the uninjured organ is acted upon*" (*Proceedings* of the Royal Society, No. 153). Here the interruption caused by the incision, while it must have completely prevented the propagation of *neural* excitation, did not prevent the propagation of the *electrical* current. Clearly therefore the simple passage *through* the cortex will explain all the effects of electrical stimulation. Clearly therefore some other proof is needed before we can assign the motor effects to an excitation of the cortex. The arguments of Dr. Ferrier (pp. 135-6) are all set at nought by Dr. Sanderson's experiment; and on the physiological and histological views now adopted I do not see how Dr. Sanderson's experiment can be brought into agreement with the motor centre hypothesis.

Nevertheless, although I say that the preliminary fact of excitation of the cortex is not proved by Hitzig and Ferrier, I do not myself doubt that fact, although my reasons will sound so paradoxical that I must wait for another article to give them expression.

George Henry Lewes

GREEK AND LATIN PHILOLOGY

Baur's Philological Introduction to Greek and Latin for Students. Translated from the German by C. Kegan Paul and E. D. Stone. (London: King and Co., 1876.)

WITH the publication of Jacob Grimm's "German Grammar" the comparative study of language entered upon a new period of existence. Bopp and the other great founders of Comparative Philology had been too busily engaged in laying the foundations of the science, in determining its main laws and principles, and in classifying whole groups or families of speech, to devote themselves to the minute and special investigation of single languages, and trace therein the application and action of the laws they had formulated. But a time came when the work of the pioneer was finished, and when it was necessary for special scholars to elaborate the details of the new science and to strengthen or modify its conclusions by a patient examination of individual dialects. The old-fashioned "philology" which had professed to analyse the forms of a language, as preserved in its literature, had proceeded upon a wrong method and had accordingly arrived at wrong results; its area of comparison was too narrow and limited, its procedure was capricious and at haphazard, and its doctrines were based rather upon individual taste than upon inductive reasoning. When it was discovered, however, that language is as much subject to the action of invariable laws as the bodily frame of man, that every sound in the words we utter is due to conditions which can be accurately gauged and determined, the "philology" of the last century underwent a complete change. It stands to the modern science of language in much the same relation as alchemy stands to chemistry. The general laws of language which had been obtained by a careful and far-reaching comparison of phenomena, were applied to explain and illuminate the facts presented by special languages, and these in their turn served to confirm or modify the generalisations already made.

Latin and Greek were naturally among the first to benefit by the new method of treatment. Thanks to the labours of scholars like Curtius and Corssen, the languages of ancient Greece and Rome have been placed in their true position, and probed, as it were, to their very roots. Their grammatical forms have been explained and simplified, their words have been traced back to an epoch when they were the common heritage of the Aryan race, and their phonetic characteristics have been made to yield fresh testimony to the truth that the place and nature of every consonant and vowel is the result of the working of undeviating laws. What, perhaps, is of still greater importance, is the line that has been drawn between the literary and the linguistic value of the two classical tongues. For purely philological purposes they are of less interest than many a savage jargon, the name of which is almost unknown, and certainly than those spoken languages of modern Europe whose life and growth can be watched like that of the living organism, and whose phonology can be studied at first hand. The more or less artificial dialect of a literary class stands outside the ever-moving current of living speech; in proportion as it is impressed with the individualism of particular writers, it becomes unsuitable for scientific treatment. The greater the literary perfection of a language, the less is its importance to the mere glottologist. The value of Latin and Greek, and more especially of Latin, lies rather in the literature they enshrine than in the linguistic features they present.

No language, however, can be wholly valueless or uninteresting to the student of human speech, and Latin and Greek, from the minuteness with which they have been studied, and the number and variety of monuments they have left behind them, have a special claim upon his attention when revivified and illuminated by scientific philology. The laws which have been ascertained by the observation of living utterance have been applied to explain the letter-changes of the classical tongues, and the comparison of their grammatical forms with those of the cognate languages has done much towards throwing light on the history of Aryan flexion and the vicissitudes through which it has passed. The innermost structure of the dead languages of Greece and Rome has been laid bare, and though there is much which will to the last resist analysis, the old mystery which enveloped the paradigms and "rules" of our school grammars has been dispelled for ever. Dr. Baur's attempt to convey the results of a scientific investigation of Greek and Latin in the shortest possible form is highly successful, and those who are unable to read German ought to be grateful for the translation of the work. The book is essentially a useful one, and we hope it will be extensively read in our schools and universities. As the author confines himself very strictly to the two classical languages, the teacher need have no fear of the pupil's mind being confused by a reference to less-known tongues. Indeed the book suffers from a neglect of Sanskrit, with which Dr. Baur does not seem to be acquainted. He has compiled the work, however, with German care and thoroughness, though, as is inevitable in a work of the kind, exception might be taken to some of his statements.

Thus no distinction is made between primitive Aryan *kw* and *k*, and the two sounds are accordingly confounded together in Greek and Latin words. *Quies*, for instance, can have no connection with the Greek *κεῖμαι*, *κωμή*, the English *home*, the Sanskrit *'si*, but must go back to a different root. So again it is very questionable whether the characteristic *r* of the Latin passive is really the reflexive pronoun *se*. In Old Bulgarian, it is true, we have *divlya se*, *diviši se*, "I admire myself," "thou admirest thyself," and in Lithuanian *dývyjů-s* "I admire myself;" but the Old Irish characteristic of the passive is also *r*, and in Old Irish *r* cannot be derived from an earlier *s*.

A. H. SAYCE

OUR BOOK SHELF

A Monograph of the Geometrid Moths or Phalænidæ of the United States (Tenth Report of the United States Geological Survey of the Territories). By A. S. Packard, Jun., M.D. (Washington, 1876.)

THIS is without question the most valuable contribution to the study of the Geometrid Moths which has ever come under our notice. The size of the work, the paper, and the classification of the introductory chapters are all that can be desired; as for the plates they are simply perfect, no pains having been spared to render them accurate even in the most minute details.[1]

After the Introduction, a chapter is devoted to the History of the Family from the time of Linnæus, a work demanding no little research, and which consequently must claim for the author the gratitude of all succeeding generations of lepidopterists: the only point in which we disagree with Dr. Packard is as regards the prominence which he gives to the "Tentamen" of Hübner, the value of which document will always be a disputed point with entomologists, inasmuch as (although twice quoted by its author in his subsequent works) it is more than doubtful whether it ever was actually published.

---

[1] To the eye of an amateur the plates would appear overcrowded, but to the working entomologist this must be one of their greatest merits.

The succeeding chapters are devoted to the differential characters of the family, to structural details, habits, development, secondary sexual characters, origin of the genera and species, and mimicry; then follow concise descriptions of the genera and species, with comparative and other valuable notes, descriptions of preparatory stages, &c.

It is a subject for congratulation, the importance of which none but the working lepidopterist can fully appreciate, that Dr. Packard has devoted six of the plates to the delineation of wing structure; most of the *generic* errors in Mr. Walker's lists must be attributed to his entire neglect of the characters offered by neuration; attention to this is sometimes the only means by which species, otherwise wholly similar, can be distinguished. The structure of the thorax, although of much importance, can rarely be attended to, as the destruction of the specimens is necessary before it can be detected; but in the examination of the wing-veins nothing is needed but a bottle of benzine, a brush, and a pocket lens, to reveal all that is required *without injury* to the insect.

In conclusion we heartily congratulate Dr. Packard on having produced a work in every respect worthy of himself and the Academy of which he is an officer.

A. G. B.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*]

Prof. Balfour Stewart on Meteorological Research

It occurs to me to make the following remarks with reference to Prof. Balfour Stewart's proposal in Nature, vol. xiv. p. 388.

I cannot see any objection either to the nomination of the council which is suggested, or to its constitution, provided each existing society is duly represented by a member who can, when circumstances seem to require it, attend and vote at any meeting of the Council in London. I quite agree with the Professor in thinking that the time has now come when our country should resolutely grapple with the data which have accumulated in past years and with those that are now being obtained. It is only by a thorough discussion of meteorological data that the importance of certain principles can be detected, and the necessity for altering the modes of observing can be demonstrated.

I do not see that the appointment of the proposed council should interfere prejudicially with the working of the different societies. While it is the duty of such societies to procure the facts, it seems to me essential in order to secure uniformity in instrumental observation, without which all deductions or generalisations from the data may be worse than useless, that a council of control should be appointed in order to lay down rules for regulating all observers. I would not give an arbitrary power to that council to compel every society to adopt their views, because I have a great aversion to centralisation in matters of science, for in some cases the branches may be more in the right than the head; but in the event of a society declining to comply with the rules issued by the council, that society should not receive Government aid excepting for work that is done in terms of the rules. I take it for granted, however, that the council would give due weight to the arguments which were adduced from time to time by the representatives of the different societies. I am further of opinion that the different bodies should not only be allowed but encouraged by Government aid to prosecute independently in their own way, any special subject which they may choose to take up.

I hold so very strongly the absolute necessity of uniformity in instrumental observation, that I should be disposed to recommend each society to adopt almost any change in the forms of instruments, in the kind of exposure, in the hours of observation, in the form of protecting boxes, or in any other matter which might be recommended by the proposed council, provided such changes were practicable, and were agreed to once for all by the other societies in this country, and by foreign nations.

I think it right to add that I am only stating my own individual convictions, and do not in any way profess to represent the opinions of the Council of the Society of which I am the honorary secretary, although I have no reason to suppose that they would take a different view.

Thomas Stevenson

Edinburgh, November 18

Ocean Currents

In the report published in Nature (vol. xiv., p. 492) of an address given at the Glasgow meeting of the British Association, September 11, by Sir C. Wyville Thomson, and revised by the author, the following passage occurs:—

"We have come to the conclusion that this great mass of water is moving from the Southern Sea, and there seems to me to be very little doubt—although this matter will be required to be gone into carefully—that the reason why this water is moving from the Southern Sea in a body in this way, is that there is a greater amount of evaporation in the North Atlantic and over the northern hemisphere generally, than there is of precipitation, whereas it seems almost obvious that in the southern hemisphere in the huge band of barometric low pressure round the south pole, the precipitation is in excess of the evaporation."

Now I quite feel that I am guilty of very great presumption in challenging in any way the theories of so great an authority as Sir C. W. Thomson, and my only excuse for the remarks I am about to make is that there are some points that I and many other seamen would like to have cleared up before we entertain such an hypothesis.

1. Have the investigations of the *Challenger* sufficiently proved that there is no compensating or return current from the North Atlantic to the South Atlantic Ocean? Especially, is it quite certain that a stream of water from the Arctic regions does not set southerly along the West Coast of Africa, *i.e.*, south of the equator?

2. Allowing that the precipitation in the Antarctic regions is greatly in excess of that in the Arctic regions, is the precipitation in the north torrid and north temperate zones less than the precipitation in the south torrid and south temperate zones?

3. Looking to the much larger distribution of land in the northern hemisphere, is it likely that the evaporation there is in excess of the evaporation in the southern hemisphere?

4. Even supposing the evaporation in the northern hemisphere to be in excess of that in the southern hemisphere, can it be shown that this vapour is carried to the Antarctic regions for condensation, or can the excess of precipitation in the Antarctic regions be accounted for in a more probable manner?

In answer to the first question I can only say that I am not able to gather from the reports of the ocean soundings and temperatures of H.M.S. *Challenger*, published by the Admiralty,[1] that it has been at all proved that there is no compensating stream of Arctic or other water.

In answer to the second question, I have never heard it disputed, and my experience as a seaman leads me to doubt the possibility of reasonably disputing, that the rainfall in the north temperate and north torrid zones is not only not less, but that it is far in excess of the rainfall in the south torrid and south temperate zones. Maury (and no matter to what extent we may differ from his theories, we must give due weight to his data) says that the total amount of rain in the north temperate zone is half as much again as in the south temperate zone.

With reference to the third question, whether the evaporation in the northern hemisphere is in excess of that in the southern hemisphere, I think the onus of proof rests with those who start the theory, but in my present state of ignorance on this subject I must confess that it is to my mind quite inconceivable. There are, with few exceptions, no large rivers in the southern hemisphere, and surely the discharge into the sea of the large rivers in the northern hemisphere must be regarded as the return to the ocean of the excess of precipitation over evaporation in the regions which they drain.

There remains the fourth question, and before trying to answer this I should like briefly to state what I think is the general or accepted belief up to the present time with reference to atmospheric currents or circulation. The trade winds are supposed to be currents from the poles which, starting from the Polar regions as upper currents, descend to the surface of the globe on the equatorial side of 30° of lat. in both hemispheres, they then travel onwards towards the belt of equatorial calms, when they meet and ascend into the upper regions of the atmosphere, whence they travel back towards the poles as upper currents, until they arrive at the calm belts of Cancer and of Capricorn, on the polar sides of which they once more descend to the surface, and are then known as the westerly winds of the temperate zones. Owing to the rotatory motion of the earth, it is impossible for these westerly winds to blow direct towards the poles, but it is clear that if you surround the Polar regions with a belt of westerly winds, that no matter what the direction of the wind may be in the Polar regions, it must, if a surface wind, be supplied by this zone; and that the winds experienced in the Polar regions are winds travelling on the surface, and are drawn from this belt of warm winds, is, I think, proved by the following extract from an account of the wintering of the *Hecla*, Capt. (Sir Edward) Parry, at Melville Island, in the year 1819–20:—

---

[1] Plate VI. Report No. 7 would appear to indicate that Arctic water does cross the equator.

"A gale of wind, from whatever quarter it might blow, was almost invariably found to raise the thermometer several degrees, even when it came from the north, as much as 14°. An east, south-east, or east-south-east wind causes the thermometer to rise 40°."

From this extract it is evident, as might be supposed, that any current of air from this zone or belt of warm westerly winds raised the thermometer considerably, but that the wind that proceeded the more directly from the ocean and had the least land to traverse was the warmest.

Maury, without attempting to prove his case, and indeed throwing the onus of proof on those who ventured to disagree with him, considers that the south-east trade winds of the southern hemisphere become the south-west winds of the north temperate zone, and *vice versâ*; that the north-east trades of the northern hemisphere become the north-west winds of the south temperate zone. I do not say that this is not the case, but if you admit that the north-east and south-east trade winds meet in the belt of equatorial calms and there ascend, it appears to be more reasonable to suppose that their currents intermingle and that their mixed volume is then drawn off north and south as required to restore the equilibrium of the atmosphere. And there is a very strong argument against Maury's hypothesis, viz., that as the south-east trades of the southern hemisphere are stronger and extend over a greater surface than the north-east trades of the northern hemisphere, and as also the north-west winds of the southern hemisphere are stronger and more continuous than the south-west winds of the northern hemisphere, it is illogical to suppose that the stronger polar current, *i.e.*, the south-east trade, feeds the weaker equatorial current, *i.e.*, the south-west winds of the north temperate zone; it would be more reasonable to suppose the reverse to be the case.

This entire theory of atmospheric currents is antagonistic to the presumption that a larger body of vapour is carried from the northern to the southern hemisphere.

Owing to the scarcity of land, and especially of very high land in the south temperate zone, not only is the precipitation less, but the vapour-carrying winds, *i.e.*, the westerly winds, are far more constant in their direction and force than are the westerly winds of the northern hemisphere. (The proportion of westerly winds to any others in the temperate zone in the North Atlantic is two to one, while throughout the south temperate zone they are so constant as to have been christened by Maury the north-west trades.)

If you once admit that these westerly winds are equatorial currents flowing towards the poles (a fact susceptible of undoubted proof), it is easy enough to account for the low barometer in the Antarctic regions, as also the larger amount of precipitation there as compared with the precipitation in the Arctic regions.

1. Because the westerly winds being much stronger and more continuous in the southern than in the northern hemisphere, the ascension of the air in the South Polar regions must be greater than in the North Polar regions.

2. Because, owing to the westerly winds of the south temperate zone parting with less of their moisture (as previously accounted for) than the corresponding winds of the north temperate zone, and also to their being stronger and more continuous, it is evident that when they meet with Antarctic cold and their vapour is condensed, the precipitation must be greater, which also involves the giving out of a much larger amount of latent heat and the consequent greater expansion and ascension of the atmosphere in the South Polar regions.

It is, I believe, universally acknowledged that all winds must blow from a high to a low barometer, *i.e.*, from a zone of high pressure to a zone of low pressure (not directly, but in a direction modified by the earth's rotatory motion). I may therefore fairly argue that the zones of low pressure at both the equator and the poles proceed from the same causes, *i.e.*, from precipitation, and from the ascension of the atmosphere, and that the lower barometer in the South Polar regions fairly accounts for the greater strength and continuity of the westerly winds of the south temperate zone, and that without these constant inequalities of pressure we should have neither trades nor westerly winds.

I have purposely from want of space avoided speaking otherwise than generally of the effect of the land on atmospheric currents, nor is it directly pertinent to my present argument.

The hypothesis of atmospheric circulation which I have very briefly sketched is in many of its features susceptible of absolute proof, more especially in the following points, viz.—

1. That the trade-winds descend to the surface of the ocean on the equatorial sides of the calms of Cancer and of Capricorn.

2. That the trade-winds ascend in the belt of equatorial calms.

3. That currents flow from the equator in the upper regions of the atmosphere in an opposite direction to that of the trade-winds on the surface of the ocean.

4. That these upper currents, flowing from the equator, descend again to the surface of the ocean on the polar sides of the calms of Cancer and of Capricorn.

5. That these equatorial currents, subsequent to their descent on the polar sides of the calms of Cancer and of Capricorn, are known as the westerly winds of the temperate zones.

And with reference to my supposition that these westerly winds ascend in the Polar regions, one strong evidence in favour of this is, that if, as I say, the ascension of the atmosphere is greater in the South Polar than in the North Polar regions, the counter or return current towards the equator must also be greater, which is the fact.

The onus lies on the promoters of the new hypothesis either to reconcile their views with the existing theory of atmospheric circulation or to supply us with a better theory, and one which shall agree equally well with well-established facts.

October 27 DIGBY MURRAY

Definiteness and Accuracy

IN my lecture on *Force* (*anté*, Sept. 21), I take for granted that the scientific use of the word is that with which all are familiar in the expression "*the parallelogram of forces.*" Hence Newton's term for *force* is *vis impressa* (Thomson and Tait's *Nat. Phil.*, § 217); though, where there is no room for mistake, he often employs the single word *vis*.

One of the main objects of my lecture was to protest against the absurd custom of translating the word *vis* in every case by the scientific word *force*. It is not easy to get an unobjectionable single word for the purpose, for most of the available words have already a semi-scientific sense attached to them. The word *power* is very flexible in its meaning, and would have been suitable had it not been already seized by the engineers. Thus (Thomson and Tait, § 216) *vis insita* is rendered *innate power*. And, giving the word as wide an application as Newton gives to *vis*, we might render *vis viva* as *active power*, which is not far from *actual* or *kinetic energy*. But this is merely a suggestion.

In *Poggendorff's Annalen* (No. 7 of this year) Prof. Zöllner translates the scientific term, "*the perpetual motion*," by "*die beharrliche Bewegung*," and thus, to his own satisfaction at least, proves me to be ignorant alike of the proper meaning of the Latin *perpetuum mobile* and of the first law of motion!

In another journal I have lately been held up to scorn, not in the main for any real or imputed fault of mine, but because my would-be critic (Mr. R. A. Proctor) happens not to know the scientific meaning of "*absolute*" measure!!

I could give many more telling instances, great and small, but I have given enough to show how needful was my contention for definiteness and accuracy. P. G. TAIT

College, Edinburgh, November 11

On the Internal Fluidity of the Earth

THE question of the solidification of the crust of the earth from the fluid interior nucleus, as referred to by Mr. Mathieu Williams, in NATURE, vol. xv. p. 5, is one which has been long since fully discussed in my papers in the *Philosophical Transactions*, the *Atlantis*, vol. i., and in a paper of which an abstract appears in the Report of the British Association for 1856. As far as I am aware, no person has controverted my conclusions as to the process of solidification of the earth. The results are, in the main, somewhat similar to those so admirably illustrated and enforced by Mr. Robert Mallet, and also such as Mr. Williams upholds in this journal.

In articles 6 and 7 of my "Researches in Terrestrial Physics," Part 1, this subject is discussed as a problem of fluid equilibrium, and the conclusion is there deduced that the fluid interior mass of the earth must consist of spheroidal strata of equal density, the density of each stratum increasing from the surface to the centre of the nucleus. The mode in which this arrangement of the fluid matter would favour the formation of a solid crust is pointed out. In Part 2 Section III., the probable law of density of these fluid strata is discussed. In Section IV. the shape of these strata is investigated, and also that of the inner surface of the shell or crust. It is shown independently of the law of density that the least ellipticity of this inner surface of the crust cannot be less than the ellipticity of its outer surface. A similar result was soon afterwards enunciated by Plana in a paper in the *Astronomische Nachrichten*. In the same section the theory of a solid nucleus in the earth originally proposed by Poisson, is examined and shown to be incompatible with physical laws.

Owing to the pointed manner in which Sir William Thomson invited discussion in a previous number of NATURE, I ventured to controvert his views as to the rigidity of the earth in a paper inserted at p. 288, vol. v. of this journal. Never at any time have I had even a doubt as to the untenable character of Sir William Thomson's views regarding the solidity of the earth.

In again reiterating this opinion in NATURE, vol. ix. p. 103, a reference to my paper was given, in which vol. vii. p. 288, is misprinted for vol. v. p. 288.

In his address at Glasgow Sir William Thomson, while maintaining his opinion as to the earth's solidity, appears to have seen the weakness of some of his former arguments by calling on his hearers (NATURE, vol. xiv. p. 428) to erase whole paragraphs of his paper on the Rigidity of the Earth, in the *Philosophical Transactions*. At the same passage of his address he refers to a hint from Prof. Newcomb, that viscosity might suffice to render precession and nutation, the same as if the earth were rigid. "This," he says, "I would not for a moment admit, any more than when it was *first* put forward by Delaunay." The *Comptes Rendus* of the Academy of Sciences of Paris for March 6, 1871, contains a paper in which my priority on this point is clearly established. In NATURE, vol. iii. p. 420, the following statement occurs:—"Paris Academy of Sciences, March 13.—M. Delaunay read a declaration stating that he acknowledged that Mr. Hennessy had used the same arguments as himself against Mr. Hopkins' theory relative to the fluidity of the interior parts of the earth."

I am willing to believe that Sir William Thomson had neither seen the *Comptes Rendus* nor the paragraph in NATURE just quoted, but it is to be regretted that a presidential address should contain an erroneous statement on a point of recent scientific history, especially when the error could be avoided by a glance at the most widely known scientific publications.

All through the portion of his address which refers to the earth's structure Sir William Thomson assumes that the views of Mr. Hopkins are established and admitted. A reference to some of the past volumes of this journal alone shows the inadmissibility of such an assumption. At pp. 45 and 182 of vol. iv. and elsewhere Mr. Hopkins' views are distinctly controverted on mechanical, physical, and geological grounds.

It appears that in the discussion on my paper in the Academy of Sciences of Paris, in which some of the most eminent mathematicians and geologists of France took part, not one of them adopted Mr. Hopkins' "Discovery of the earth's solidity." As far as I am aware, this "discovery" is not adopted anywhere on the continent of Europe. I have studied with as much care and attention as I could give to them, the mathematical and physical researches of Mr. Hopkins and Sir William Thomson relative to this subject, and for reasons already partly unfolded in this journal at vol. v. p. 288 and vol. iv. p. 182, I continue to firmly adhere to the almost diametrically opposite conclusions long since enunciated in the publications referred to at the outset of this communication.

HENRY HENNESSY

Royal College of Science, Dublin

The Age of the Rocks of Charnwood Forest

I SEE that in Mr. Woodward's "Geology of England and Wales," recently published, the rocks of Charnwood Forest, in Leicestershire, are (with some hesitation) referred to the "Laurentian" series, Prof. Ansted and Dr. Holl being quoted as authorities. The reviewer in the recent number of the *Saturday Review* adopts the same opinion; at the same time it is proper to add that Mr. Woodward states in another place (p. 31) that the Charnwood Forest rocks "may be of Cambrian age," so that the reader is left to take his choice.

For my part I confess to being at a loss to understand on what grounds these old rocks can be referred to any other than the Cambrian period. The evidence in any case is small, but what there is points to this conclusion.

In the first place it ought to be remembered that the age of these rocks was first indicated by Prof. Sedgwick, whose opinion on such a question should not be disregarded unless on very substantial grounds. Sedgwick's opinion of their age was founded almost entirely on lithological grounds, and no one was better qualified to recognise the representatives of the Welsh Cambrians, though rising up isolated amongst much newer formations in the heart of England. Prof. Jukes, in his description of the geology of Charnwood Forest, appended to Porter's "History," adopted the same view, in which the officers of the Geological Survey, including the present Director-General, who made a personal examination of the forest rocks, concurred (see "Geology of the Leicestershire Coal Field," Mem. Geol. Survey, 1860). I am not aware that they have changed their views owing to what has been since written on the subject.

As regards the determination of the age of these rocks, if it is impossible to prove them to be of Cambrian age, there are very good grounds for concluding they are not of "Laurentian" age, assuming that term to refer to the fundamental gneiss of the north-west Highlands and Isles of Scotland. These rocks consist, according to the description of Murchison, of coarsely crystalline gneiss, full of granite veins. They are everywhere intensely metamorphosed. Now, this is far from being the case with the Charnwood Forest rocks. Generally they are no more metamorphosed than are the Cambrian beds of the Longmynd, or of Llanberis. True "gneiss" is very exceptional, and metamorphic action is quite local, and is chiefly confined to one district. Any argument, therefore, drawn from lithological resemblance to the rocks of the typical district entirely fails; and I cannot admit that the occurrence of rocks (syenite, &c.) resembling those of the Malvern Hills, is of any force in this question, as it is very far from having been proved that the Malvern Rocks are of Laurentian age.

As regards evidence founded on organic remains, it is of the most meagre kind, but whatever the obscure markings on the slates of Charnwood may really be, they are certainly not those of *eozoon*. From whatever side, therefore, the question is viewed, there appears to be no good ground for departing from the view regarding the age of these rocks originally adopted by Sedgwick.

Geological Survey Office, Dublin, November 3

Mind and Matter

MR. SPALDING in his critique on Maudsley's "Physiology of Mind" (NATURE, vol. xiv. p. 541), while admitting that "the dependence of consciousness on nervous organisation, seemed," by the science of nerve physiology, "to be fairly established," stated that the difficulty of conceiving *how* consciousness stood related to the material organism, was a difficulty which had not yet been overcome.

Might not this problem be solved somewhat thus:—It is as easy to predicate subjectivity (or susceptibility to consciousness) of one entity called matter, as of another entity called soul or spirit. It is no more difficult to conceive of matter being subjective than of spirit being subjective.

Again, energy accompanies matter in all its forms, and yet *how* it is related to the entity called matter, is no less mysterious than how subjectivity may be a property of matter. Energy moreover may be divided, Why may not subjectivity? Energy exists in isolated as well as in grouped and combined forms, Why may it not be so with subjectivity? Energy exists in a potential form when opposing forces neutralise each other—that condition of matter we call rest. May not subjectivity exist in a potential form when opposite kinds of subjective states tend to establish themselves in the same material mass—so constituting that condition of matter which we call unconsciousness? Energy is only kinetic or active, that is, only shows itself in the form best realised by us when one force has of all the others the ascendency, or is the expression of their united tendencies. May it not be so of subjectivity that it only develops into its active and best recognised form when one kind of subjective state has the ascendency, or is the expression of the united subjective states? Thus, as energy potential is rest, so subjectivity potential is unconsciousness. As kinetic energy is motion, so active subjectivity is consciousness.

In this way while all matter is subjective or susceptible of consciousness, this subjectivity seems to exist in the potential form only in all but organisms possessed of a nervous system. In the active nerve fibre the subjectivity of matter appears alone to be active or conscious, while the complex organisation of the nervous systems of the higher animals alone permits of matter rising to the powers of mind by harmoniously combining many subjective states so as to build them up into perception, understanding, memory, imagination, reason, invention, and judgment.

WM. S. DUNCAN

Stafford, November 9

Meteor

I OBSERVED from a high point overlooking the Weald, on the night of November 6, about the time Mr. Nostro mentions, a large meteor fall from a point a little below the zenith in the northern sky. It burst twice, emitting bluish sparks in doing so, once shortly before it disappeared, and the second time on its disappearing. Could it have been the same meteor seen from different positions?

I could not be positive to a point or two as to its exact magnetic bearing, but I do not think I am far wrong in saying it fell almost due north from where I observed it.

CECIL H. SP. PERCEVAL

Pulborough, November 18

THE PRESENT STATE OF MATHEMATICAL SCIENCE

AT the meeting of the Mathematical Society on November 9, Prof. H. J. S. Smith gave an address on this subject, in which he excluded all reference to applied mathematics. "I shall regard it," he said, "as a fortunate circumstance if my successor when he, in his turn, is looking round for a subject for his own presidential address, should be attracted by a domain on which I must myself decline to enter, but of which he, better perhaps than anyone among us, is fitted to give us a clear and comprehensive view." He professed to offer only fragmentary remarks, "hoping that even such fragmentary remarks may not be without their use if they serve to remind us of the vastness of our science, and yet of its unity; of its unceasing development, rapid at the present time, promising to be still more rapid in the immediate future, and yet deriving strength and vitality from roots which strike far back into the past, so that the organic continuity of its gigantic growth has been preserved throughout. In every science there is a time and place for general contemplations, as well as time for minute investigations. And it is a rule of sound philosophy that neither of these shall be neglected in its proper season ('itaque alternandæ sunt istæ contemplationes,' says Lord Bacon, 'et vicissim sumendæ ut intellectus reddatur simul penetrans et capax')."

Touching upon a charge brought against the *Proceedings* of the Society that its memoirs "have shown and still continue to show a certain partiality in favour of one or two great branches of mathematical science to the comparative neglect and possible disparagement of others," it might be rejoined "with great plausibility that ours is not a blamable partiality but a well-grounded preference. So great (we might contend) have been the triumphs achieved in recent times by that combination of the newer algebra with the direct contemplation of space which constitutes the modern geometry—so large has been the portion of these triumphs, which is due to the genius of a few great English mathematicians—so vast and so inviting has been the field thus thrown open to research, that we do well to press along towards a country which has, we might say, been 'prospected' for us, and in which we know beforehand we cannot fail to find something that will repay our trouble, rather than adventure ourselves into regions where, soon after the first step, we should have no beaten tracks to guide us to the lucky spots, and in which (at the best) the daily earnings of the treasure-seeker are but small, and do not always make a great show, even after long years of work. Such regions, however, there are in the realm of pure mathematics, and it cannot be for the interest of science that they should be altogether neglected by the rising generation of English mathematicians. I propose, therefore, in the first instance, to direct your attention to some few of these comparatively neglected spots."

The foremost place is assigned, by Prof. Smith, to the Theory of Numbers. "Of all branches of mathematical knowledge this is the most remote from all practical application, and yet, perhaps more than any other, it has kindled an extraordinary enthusiasm in the minds of the greatest mathematicians. We have the examples of Fermat, of Euler, of Lagrange, Legendre, of Gauss, Cauchy, Jacobi, Lejeune Dirichlet, Eisenstein, without mentioning the names of others who have passed away, and of some who are still living. But, somehow, the practical genius of the English mathematician has in general given a different direction to his pursuits; and it would sometimes seem as if we measured the importance of the subject by what we find of it in our best treatises of algebra, or as if we accepted the denunciations of Auguste Comte, and regarded the votaries of the higher arithmetic as reprobate of positive science, as moving in a vicious circle of metaphysical ideas, and as guilty of a great crime against humanity in the pursuit of knowledge beyond the limits of the useful. . . . I would rather ask you to listen to what is recorded of the great master of this branch of science."

Gauss (we are told by his biographer) held mathematics to be the queen of the sciences, and arithmetic to be the queen of mathematics—"She sometimes condescends to render services to astronomy and other natural sciences (so spoke the great astronomer and physicist); but under all circumstances the first place is her due." A citation was also made from Jacobi's Life of Göpel: "Many of those who have natural vocation for pure mathematical contemplation find themselves in the first instance attracted by the higher parts of the theory of numbers."

Three great departments of arithmetic were instanced: The arithmetical theory of homogeneous forms (or quantics)—"It is a memorable fact that some of the greatest conceptions of modern algebra had their origin in connection with arithmetic, and not with geometry or even with the theory of equations." In the "Disquisitiones Arithmeticæ" are given for the first time the characteristic properties of an invariant and a contravariant (for ternary quadratic forms). "But the progress of modern algebra and of modern geometry has far outstripped the progress of arithmetic; and one great problem which arithmeticians have now before them is to endeavour to turn to account for their own science the great results which have been obtained in the sister sciences. How difficult this problem may prove is, perhaps, best attested by the little advance that has been made towards its solution." As an example, the researches of Cayley, Bachmann, and Hermite on the algebraical problem of the automorphies of a quadratic form, containing any number of indeterminates, were alluded to. Omitting many other points which were brought out, we can only mention the second department of arithmetic, the theory of congruences. In connection with this division, Prof. Smith also dwelt in detail upon the subject of complex numbers. "The last part of arithmetical theory to which I would wish to direct the attention of some of the younger mathematicians of this country is the determination of the mean values, or the asymptotic values of arithmetical functions. This is a field of inquiry which presents enormous difficulties of its own; it is certainly one in which the investigator will not find himself incommoded or crowded out by the number of his fellow-workers. 'Nemo est fere mathematicorum,' said Euler, in the last century; 'qui non magnam temporis partem inutiliter consumpserit in investigatione numerorum primorum;' but I do not think that (as a rule) the mathematicians of the present day have any reason to reproach themselves on this score." The speaker then pointed out what had been done in this direction since the days of Euler. "I do not know that the great achievements of such men as Tchebychef and Riemann can fairly be cited to encourage other and less highly gifted inquirers, but at least they may serve to show two things—first, that nature has fixed no impenetrable barrier to the further advancement of mathematical science in this direction; and secondly, that the boundary of our present knowledge lies so near us that at any rate the inquirer has no very long journey to take before he finds himself in the unknown land. It is this peculiarity, perhaps, which gives such perpetual freshness to the higher arithmetic. It is one of the oldest branches—perhaps the very oldest branch—of human knowledge, but yet its tritest truths lie close to some of its most abstruse secrets. I do not know that any more striking example of this could be furnished than by the theorem of M. Tchebychef. To understand his demonstration requires only such algebra and arithmetic as are at the command of many a schoolboy; and the method itself might have been invented by a schoolboy with the genius of Pascal or of M. Tchebychef."

Passing on to other branches of analysis, Jacobi's method of approximation ("a natural extension of the theory of continued fractions"), Lejeune Dirichlet's researches on complex units and his great generalisation of the theory of the Pellian equation, Liouville's treatment of irrational quantities, Lambert's proofs that neither π nor π^2 nor e are rational with M. Hermite's extensions, who, though he has proved that e is a transcendental irrational, declines entering on a similar investigation for the number π, but leaves this to others, adding, "Nul ne sera plus heureux que moi de leur succès, mais, croyez m'en, il ne laissera pas que de leur en coûter quelques efforts"—all came in for a notice.

Another class* of questions mentioned were those which relate to the transcendental or algebraic character of developments in the form of infinite series, products, or continued fractions. The theorem of Eisenstein and M. Hermite's recent investigation of it, lately communicated to the Society, "are amply sufficient to awaken the expectation of great future discoveries in this almost unexplored field of inquiry."

Amongst important objects for mathematicians to set before them were named the advancement of the integral calculus ("confessedly all important in the applications of mathematics to physics"). In this connection the theory of differential equations and of singular solutions came in for a detailed notice, as also did the subject of elliptic functions.

Towards the close of the address, Prof. Smith said: "I am convinced that nothing so hinders the progress of mathematical science in England as the want of advanced treatises on mathematical subjects. We yield the palm to no European nation for the number and excellence of our text-books of the second grade; I mean of such text-books as are intended to guide the student as far as the requirements of our University examinations in honours are concerned. But we want works suitable for the requirements of the student when his examinations are over—works which will carry him to the frontiers of knowledge in certain directions, which will direct him to the problems which he ought to select as the objects of his own researches, and which will free his mind from the narrow views which he is apt to contract while getting up work with a view to passing an examination, or, a little later in his life, in preparing others for examination. Can we doubt that much of the preference for geometrical and algebraical speculation which we notice among our younger mathematicians is due to the admirable works of Dr. Salmon; and can we also doubt that if other parts of mathematical science had been equally fortunate in finding an expositor, we should observe a wider interest in, and a juster appreciation of, the progress which has been achieved?

There are, of course, other works besides those of Prof. Cayley and Dr. Salmon to which I might refer; there is, for example, the work of Boole, on Differential Equations; and there are the great historical treatises of Mr. Todhunter so suggestive of research, and so full of its spirit; we have also a recent work by the same author on the functions of Laplace, Lamé, and Bessel. But the field is not nearly covered . . . There are at least three treatises which we sadly need, one on definite integrals, one on the theory of functions in the sense in which that phrase is understood by the school of Cauchy and of Riemann, and one (though he should be a bold man who would undertake the task) on the hyperelliptic and Abelian integrals.

Geometry, and some other subjects, were hardly more than mentioned.

> "Verum hæc ipse equidem spatiis exclusus iniquis
> Prætereo, atque aliis post memoranda relinquo."

"In these days, when so much is said of original research, and of the advancement of scientific knowledge, I feel that it is the business of our Society to see that, so far as our own country is concerned, mathematical science should still be in the vanguard of progress. I should not wish to use words which may seem to reach too far, but I often find the conviction forced upon me that the increase of mathematical knowledge is a necessary condition for the advancement of science, and, if so, a no less necessary condition for the improvement of mankind. I should tremble for the intellectual strength of any nation of men whose education was not based on a solid foundation of mathematical learning, and whose scientific conceptions, or in other words, whose notions of the world and of the things in it, were not braced and girt together with a strong framework of mathematical reasoning. It is something to know what proof is, and what it is not; and where can this be better learned than in a science which has never had to take one footstep backward, and which is the same at all times and in all places. . . . I shall be more than satisfied if anything that may have fallen from me may induce any one of us to think more highly than he has hitherto done of the first and greatest of the sciences, and more hopefully of the part which he himself may bear in its advancement."

The address, delivered in the author's effective style, was frequently applauded by an appreciative group of members. On the proposal of Prof. Cayley it was resolved (with the author's consent) that the address should be printed in the *Proceedings*.

THE AUSTRIAN ARCTIC EXPEDITION[1]

IN addition to the points referred to in our article of last week, there are several others touched on in Lieut. Payer's work, which, in view of some of the results of our own expedition, it may not be unprofitable to dwell upon. Indeed a comparison between the observations and deductions of so keen and accomplished an observer as Payer and those of Capt. Nares's party, when these have been fully published, might, we think, lead to a distinct advance of our knowledge of the Arctic basin. And here we may be allowed to say that when so experienced and cautious an Arctic explorer as Payer expresses a decided conviction, as we understand he has done, that Capt. Nares acted in the only way possible under the circumstances, and no expedition could have been better conducted, surely it is a strong proof that our expedition was essentially successful.

The translator in his Preliminary Notice refers to the ice-experiences of the Austrian expedition as compared with those of the English expedition, and finds in many points a striking similarity between them. We have already referred to the tedious journey of the *Tegetthoff* party over the piled-up ice after they abandoned the ship, when they were able to make only nine miles in two months, suggesting inevitably the now well-known and ever-memorable experiences of Capt. Markham and his party. To all appearance this retreat of the Austrians was over a part of the same field which held the *Tegetthoff* in its grip, and which those on board saw in the very process of changing from a level floe to mountains of ice, as Payer calls them. It seems to be inferred by some that the ice of such enormous thickness met with by Markham was the result of the freezing of layer on layer through a long succession of years, since the last glacial epoch as it has been put—only of course a violent figure of speech. This notion we believe to be open to question.

"The thickness which ice acquires in the course of a winter," Payer says, in his instructive chapter on "The Frozen Ocean," "when its formation is not disturbed, is about eight feet. In the Gulf of Boothia, Sir John Ross found the greatest thickness about the end of May; it was then 10 feet on the sea and 11 feet on the lakes. In his winter harbour in Melville Island Parry met with ice 7 or 7½ feet thick; and Wrangel gives the thickness of a floe on the Siberian coast, which had been formed in the course of a winter, at 9½ feet. According to the observations of Hayes the ice measured 9 feet 2 inches in thickness in Port Foulke. He estimates it, however, by implication, far higher in Smith's Sound: 'I have never seen,' he says, 'an ice-table formed by direct freezing which exceeded the depth of eighteen feet.' The rate at which ice is formed decreases as the thickness of the floe increases, and it ceases to be formed as soon as the floe becomes a non-conductor of the temperature of the air by the increase of its mass, or when the driving of the ice-tables one over the other, or the enormous and constantly accumulating covering of snow places limits to the penetration of the cold. While therefore the thickness which ice in free formation attains is comparatively small, fields of ice from 30 to 40 feet high are met with in the Arctic Seas; but these are the result of the forcing of ice-tables one over the other by pressure, and are designated by the name of 'old ice,' which differs from young ice by its greater density, and has a still greater affinity with the ice of the glacier when it exhibits coloured veins."

It seems evident, then, that the palæocrystic ice, like the ice in which the *Tegetthoff* was beset, is not the result of direct freezing of layer on layer, but to a great extent the result of pressure, by which a wide field may be broken up, and the pieces so piled over each other as to form impassable mountains and valleys. How this is accomplished may be learned from the impressive description of Lieut. Payer:—

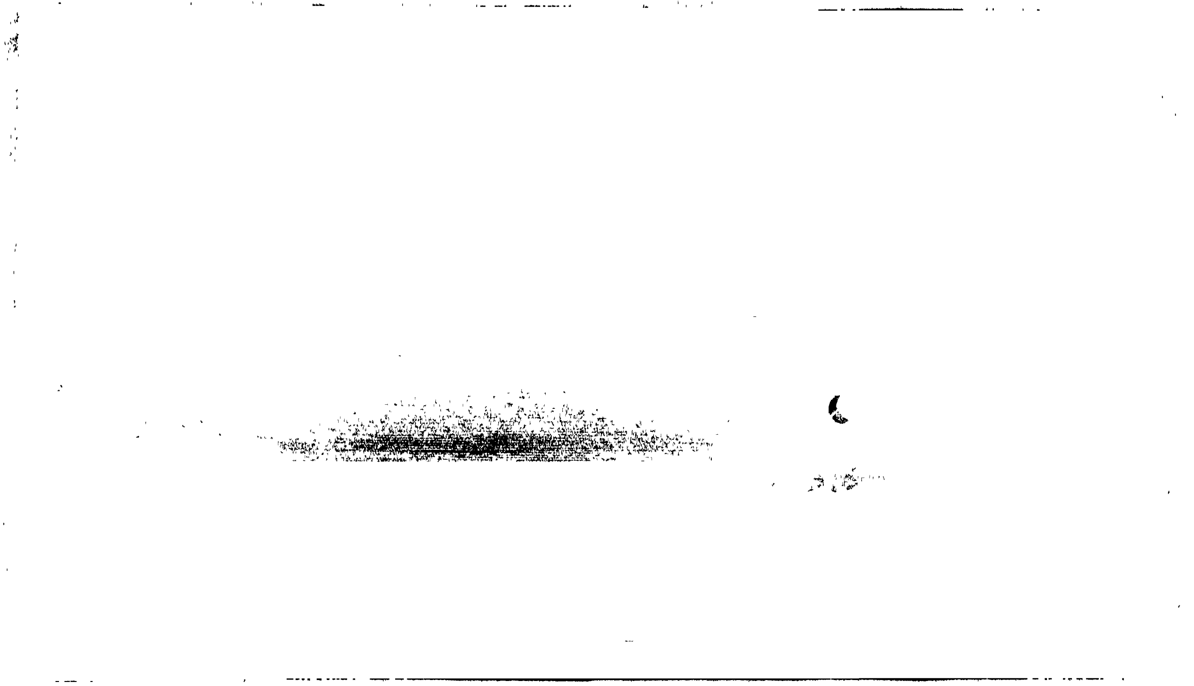
"A dreadful day was the 13th of October—a Sunday; it was decisive of the fate of the expedition. . . . In the morning of that day, as we sat at breakfast, our floe burst across immediately under the ship. Rushing on deck, we discovered that we were surrounded and squeezed by the ice; the after part of the ship was already nipped and pressed, and the rudder, which was the first to encounter its assault, shook and groaned; but as its great weight did not admit of its being shipped, we were content to lash it firmly. We next sprang on the ice, the tossing tremulous motion of which literally filled the air with noises as of shrieks and howls, and we quickly got on board all the materials which were lying on the floe, and bound the fissures of the ice hastily together by ice-anchors and cables, filling them up with snow, in the hope that frost would complete our work, though we felt that a single heave might shatter our labours. But, just as in the risings of a people, the wave of revolt spreads on every side, so now the ice uprose against us. Mountains threateningly reared themselves from out the level fields of ice and the low groan which issued from its depths grew into a deep rumbling sound, and at last rose into a furious howl as of myriads of voices. Noise and confusion reigned supreme, and step by step destruction drew nigh in the crashing together of the fields of ice. Our floe was now crushed, and its blocks piled up into mountains, drove hither and thither. Here they towered fathoms high above the ship, and forced the protecting timbers of massive oak, as if in mockery of their purpose, against the hull of the vessel; there masses of ice fell down as into an abyss under the ship, to be engulfed in the rushing waters, so that the quantity of ice beneath the ship was continually increased, and at last it began to raise her quite above the level of the sea."

It can easily be imagined that were ice which had been subjected to such a process to get jammed permanently into any position, it would become a formidable barrier to all passage over or beyond it. But the question arises—Does such mountainous ice never break up? Are these areas in the Arctic basin eternally covered with such ice, or is there a perpetual movement going on all over the Polar region? That the palæocrystic ice is not a fixture in the position in which our expedition found it we endeavoured to show in a previous article; if the observations of Hall and his party are to be trusted, and we believe they are perfectly reliable, the southern latitude of the formidable barrier must change considerably. That there is an open Polar Sea we do not think there is the least ground for believing. So far as we have seen, its only serious advocate is Dr. Hayes, one of its surviving "discoverers," and it is not to be at all wondered at that he should cling fondly to his pet theory. It is to be regretted that he did not wait for Capt. Nares's report, ere he rushed to an attack of the conduct and results of the English expedition; he might then have spoken more coolly and courteously. At Cape Fligely Lieut. Payer came upon a large stretch of open water which one less well-informed and with less of a scientific training might at once have eagerly taken for the border of an "open Polar Sea." Not so Lieut. Payer, who has no faith in such a dream; he took his open water for what it undoubtedly was seen to be on careful inspection, a polynia, or water-hole. Here is his opinion on the question. After referring to the experiences of previous explorers he says:—

"Those propitious ice-years amount, therefore, to nothing more than a greater recession of the outer ice-barrier—trifling when compared with the mighty whole—or to an increased navigability of certain coast waters, or to a local loosening of the inner polar ice-net. In reality the whole Arctic Sea, with its countless ice-fields and floes, and its web of fine interlacing water-ways, is nothing but a net constantly in motion from local, terrestrial, or cosmical causes. All the changes and phenomena of this mighty network lead us to infer the existence of frozen seas up to the Pole itself; and according to my own experience gained in three expeditions I consider *that the states of the ice between* 82° *and* 90° N.L. *will not essentially differ from those which have been observed south of latitude* 82°; *I incline rather to the belief that they will be found worse instead of better*."

---

[1] "New Lands within the Arctic Circle. Narrative of the Discoveries of the Austrian Ship *Tegetthoff* in the Years 1872–1874." By Julius Payer, one of the Commanders of the Expedition. Maps and numerous Illustrations. Two vols. (London: Macmillan and Co., 1876.) Continued from p 65.

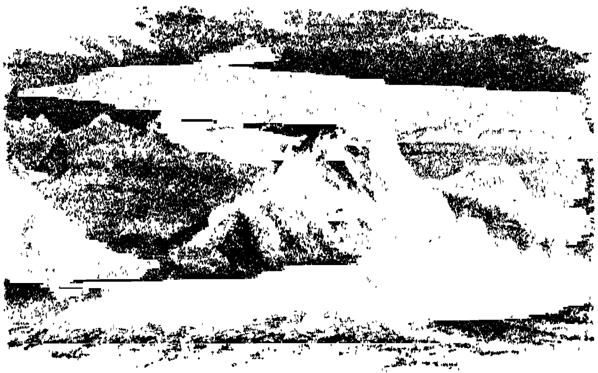


Noon on December 21, 1873

This is almost prophetic of the results obtained by the English expedition, and is one more proof of the accuracy of their observations. Still that there are one or more bodies of open water in the polar basin, bodies which are never permanently frozen over seems evident from even the comparatively little information we have.

Icebergs at the Base of the Middendorf Glacier.

The ice seems to be in almost constant motion within the basin except in the immediate vicinity of coasts, and in order that this may happen there must be open spaces somewhere. The southern edge of the Novaya Zemlya ice varied in the years 1871-2-4 by about 100 miles, and Hall saw only water and easily penetrable ice where our sailors were baffled by the impenetrable ancient ice. This simply shows that there is a constant shifting of the southern ice border, but that its position and that of whatever open water exists within the basin itself will ever be so favourable as to enable a ship to navigate to the Pole is to us quite incredible. That the polar ice, like all other phenomena, is subject to some laws in its movements, we must believe; what these are we as yet know not, but that



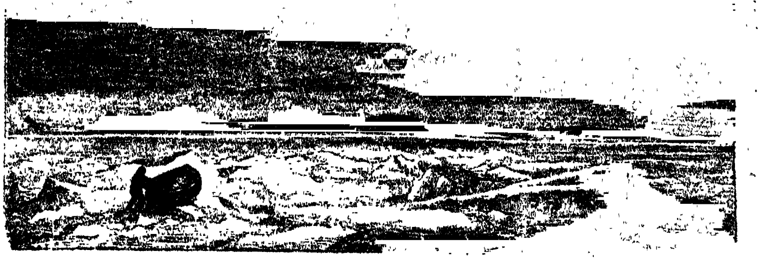
The View from Cape Tyrol. Collinson Fiord—Wiener Neustadt Island

they have some connection with the sun-spot period, is most likely. These and other points can only be satisfactorily settled by an international ring of Arctic observatories.

As to the future of the polar question, Payer believes that the days of large expeditions are past, and that until we are able to devise some aërial method of reaching or crossing the polar area, we ought to content ourselves with completing our knowledge of what has been discovered, and carrying on observations on the plan proposed by Lieut. Weyprecht. Still that there will be attempts to penetrate farther northwards we think is very likely; and should any other nation surpass the latitude attained by Markham's party, or even find the secret of the pole itself, the English nation will not grudge it the honour. Ballooning has, since the return of our expedition, been frequently advocated as a means of polar exploration, and it may be interesting to mention that more than twenty years ago Parry used balloons as a means of scattering messages while his ship was frozen up.

The meteorological observations of the Austrian expedition are likely to be of the greatest value when fully published. Some data are given in the appendix, and a few extracts in the text from Admiral von Wüllerstorf-Urbair's analysis of them.

The observations made use of by Admiral v. Wüllerstorf-Urbair are those of the winds, including both direction and force, and such of the astronomical observations as served to fix the positions of the ship while it drifted in the ice from Novaya Zemlya to Franz Josef Land. The results were published in two charts in Petermann's *Mittheilungen* in 1875, which show the positions of the ship from August 24, 1872, to November 1, 1873, and the mean direction of the wind at the same times. They are deeply interesting from the light they seem to cast on the air and sea currents over this portion of the Arctic Sea. Speaking generally, during the first half of the course, or from October to the beginning of February, westerly and southerly winds prevailed and, during the latter half easterly and northerly winds; these winds being, it may be remarked, in accordance with the mean distribution of atmospheric pressure for the different regions and months respectively. The ice-drift followed approximately a similar course, subject apparently, however, to deflections which may be supposed to be due to the coasts of Novaya Zemlya and Franz-Josef Land, and to powerful ice-drifts from the Kara Sea and from the sea to eastward of Franz-Josef Land. From the investigation so far as carried out, it is concluded that in the sea lying between Novaya Zemlya and Franz-Josef Land the existence of a sea-current is probable, the prevailing winds being also in accordance with this supposition, and that a great expanse of sea to the north and north-east of Novaya Zemlya is also probable.



Parhelia on the Coast of Novaya Zemlya.

Ice Pressure in the Polar Night.

We look forward with much interest to the publication of the detailed account of the meteorological work of this expedition for the elucidation of several questions, such as the remarkable changes in the course of the ice-drift in the end of 1872 and beginning of 1873, viewed in connection with the weather of Northern Europe at the time. Thus, at Archangel the barometer rose on November 4 to 30·476 inches, fell on the 8th to 29·118 inches, and on the following day the temperature rose to 33°·8; immediately after this the wind shifted from S.W. to N.E., temperature fell to −13°·0 on the 11th, and the barometer rose to 30·717 inches on the 13th. The great deviation in the course of the ice-drift, which extended from November 9, 1872, to February 2, 1873, began with this rise of the barometer, shift of the wind, and fall of the temperature at Archangel. Again, during January, 1873, the mean height of the barometer was 30·027 inches at Archangel; 29·826 inches at Kem, on the west coast of the White Sea; 29·838 inches at Vardö and 29·770 inches at Alten, both in the extreme north of Norway; 29·229 inches at Thorshavn, Farö; and 29·131 inches at Stykkisholm, Iceland. In connection with the remarkably disturbed state of the atmosphere in this arctic and sub-arctic region, as indicated by these figures, it is to be remarked that it was just during this time that the most remarkable deviation from the general course of the ice-drift took place. On January 2 the course suddenly changed from a north-north-westerly direction to a direction almost due east, which was steadily maintained untill February 2, when it again suddenly changed to a north-north-westerly direction, the ship having drifted between these dates from 66° 50′ to 73° 20′ long. E.

No more powerful argument, we think, could be adduced than these facts for the establishment of a series of Arctic observatories; the influence of the changing Arctic conditions on the climate of Europe is unmistakable, and a knowledge of what these conditions are, and what laws they are subject to, would undoubtedly be of great practical value.

The chapter on the aurora is very interesting; it contains the valuable observations by Lieut. Weyprecht, which we published in NATURE, vol. xi., p. 368. Contrary to the experience of our own expedition and others in high latitudes on the American side, the auroras seen by the *Tegetthoff* were remarkably brilliant. No sound of any kind was observed to accompany the phenomenon.

Lieut. Payer's work, though professing to be only a popular narrative of the expedition, contains, it will be seen, much of great scientific interest, and we repeat that in the discussion of the results of our own expedition, his observations and conclusions will be found of real value.

OUR INSECT FOES

THE receipt of the eighth Annual Report on the noxious, beneficial, and other insects of the State of Missouri, and the conferences on insect destruction in connection with the Paris Insect Exhibition recently held, bring again prominently forward the question—what are we to do to cope with our insect foes? Mr. Riley, the State entomologist for Missouri, in his report, gives account of five noxious insects—the Colorado Potato-beetle (*Doryphora 10-lineata*, Say), the Canker Worms (*Paleacrita vernata*) and (*Anisopleryx pometaria*), the genus Paleacrita being a new one; the Army Worm (*Leucania unipuncta*, Han.), the Rocky Mountain Locust (*Caloptenus spretus*, Tho.), and the Grape Phylloxera. In each case an account is given of the estimated amount of damage done, and the proposed methods for attacking the enemy, as well as the life history, so far as is known, of the insect itself. While the damage by Colorado Beetle during 1875 was less than usual, owing to the excessive wet drowning the broods, and the Army Worm did comparatively little damage, the devastation caused by the locust was unusually heavy. Mr. Riley gives separately the accounts of different counties of the State.

One or two quotations will serve to indicate the gravity of the question, what is the remedy to be adopted? For example, in the account of Jackson County—"All kinds of growing crops disappeared before the black dead line of their advance. . . . With all the crops of wheat, rye, oats, flax, clover, corn, gardens, and pastures consumed in defiance of every human effort to stay the general devastation, the fields being as bare as the public roads, the outlook was gloomy beyond description. Many gave up in despair and left the county." So great was the destitution that relief meetings were held, the story of suffering being that many were reduced to a scanty supply of bread. Take again Buchanan County (written June 7): "The crops are all destroyed now, together with meadows and pastures." Again, Bates County: "all our crops and pastures eaten off until they are as bare as in mid-winter." St. Clair County: "The terrible sights of the cruel war are now being outdone by the cruellest of sights—starvation." And so on with a large proportion of the counties. Some counties were so fortunate as to escape with small damage. The total loss to the State for the year is set down at $15,000,000. A day of supplication to Almighty God, with fasting, was ordered on June 3 by the Governor. Mr. Riley, however, repudiates the idea that this calamity was a divine visitation, and quotes from a speech he made in the previous May, in which he said, "When I suggested last winter that a law should be passed offering a bounty for the eggs, the idea was ridiculed, but the people see now how wise such a course would have been. A few thousand dollars appropriated by the legislature for the purpose would have been the means of averting the present injury" (p. 93). The accounts given from some States describe the air as thick with locusts on the wing, so that darkness as of twilight was produced. We fortunately in England do not suffer from the locust, but we may learn a lesson as to what is the course considered necessary for coping with insect ravages. Nothing short of an Act of Congress to enforce the action to be taken seems to be regarded as of any real use. Although districts have previously suffered to the verge of starvation, we find Mr. Riley saying (p. 132), "It is very evident that if anything can be done at all in averting this evil, it must be done by national means. The advantage of having the matter properly investigated by the national government has been repeatedly urged by many prominent persons in the west best competent to judge." Societies have recently passed resolutions, the resolutions have led to a memorial, and the memorial to the introduction of two bills into Congress. The one proposed the appointment of a commission of three by the Commissioner of Agriculture, who are to report on the best means of preventing incursions of the locusts. The other proposed that the Secretary of the Interior shall appoint a board of three entomologists on the nomination of the National Academy of Sciences. They were to report on noxious insects generally, and "as soon, also, as the information gathered shall enable them, the commissioners shall compile practical instructions for the suppression of the different insects referred to." The amendments to both these bills were finally adopted in this form:—"That it shall be the duty of the Commissioner of Agriculture to investigate and gather information relative to those insects, &c. . . . and to make public from time to time such information and practical instructions for the suppression of the different insects." This, Mr. Riley remarks, is what people outside the senate were in the habit of supposing to be his duty. The chief practical suggestion Mr. Riley has to make is that State aid should be given for bounties of so many cents a bushel for the young insects while hatching. It will be some time, however, before we shall know what the Commissioner of Agriculture proposes to have done. Dr. Leconte, in his address before the American Association for the Advancement of Science at Detroit last year, urged the need for a law to compel farmers to destroy insects on their lands at a particular time.

Let us now turn to what has been done in France. We have already in a note, a few weeks ago, mentioned the way in which it is sought, through the elementary schools, to spread a knowledge of practical entomology. It remains now to refer to the attempts at legislation. As far back as 1732 a law was passed ordering farmers and landowners to destroy the caterpillars on their lands under a penalty of fifty livres. This 1732 law was renewed by prescriptions in 1777 and 1787. During the revolution, fines were abolished and rewards for destruction were substituted. It was found this plan was of no practical use. In 1796 the law known as that of 26 Ventose, an. iv. was passed. It enacted that the destruction of caterpilliars should be effected by the owners or tenants of land, and that if they neglected to do it the adjoints were to have it down and recover the expense from the negligent owner or tenant. The public lands were to be done at public cost, and the *Commissaires du Directoire Exécutif* were to visit the districts to see that all been carried out. The penalty fixed was not less than three nor more than ten days labour, in addition to repaying the expenses incurred by the employment of workmen. This law, made in 1796, is still the law for France, though practically it is not put in force. The local officials were found to hesitate in the performance of the duties laid down for them, those even who were disposed to carry them out saw how useless it was for one district to be cleared while adjoining districts remained as practically breeding grounds for the pests. That a workable law is wanted has been shown by the attempts in 1839, 1849, 1851, and 1872, to introduce a bill that shall repeal the old law and substitute one that could be worked. The first two attempts fell through in consequence of dissolutions, the *coup d'état* interfered with that of 1851, but the proposal of 1872 was considered in March, 1873, passed a first reading December, 1874, a second on January 5, 1875; while the amendments were under discussion, however, M. Ducuing, the proposer, died. Last May a *projet du loi*, based on M. Ducuing's proposal, and somewhat modified in accordance with the discussion on the amendments, was introduced by MM. de la Sicotière, Grivart, and the Comte de Bouillé. They propose the law to apply to all harmful insects, the duty of destruction being imposed on the landowners and tenants. The time of the year to be selected for the destruction is to be made known by the prefect who will have scientific advice; the maires and commissionaires are to see that the law is carried out; in cases of neglect they are to have the work done, and recover the cost from those who should have done it. Special provisions are made for public lands, lands bordering on roads and railways. The fines are to range from 10 to 25 francs for a first offence. The articles that refer to the protection of birds that eat insects are not applicable to the wants of England as we already have legislation on that subject. But for years the want of some definite action to cope with "our insect foes" has been over and over again the subject of articles, speeches, and letters to the public press. The experience of France and America is that farmers must be compelled to look to their own interests. The department of practical entomology under the direction of the Committee of Council on Education is designed to give information regarding England's insect pests, but the question remains—How is the knowledge to be applied for the practical good of the country?

In connection with this important subject, the following extract from a Memorandum of the Canadian Minister of Agriculture, in reference to a despatch of the Secretary of State for the Colonies, on the subject of the Colorado Beetle is interesting:—

"The remedies which necessity has taught on this side of the Atlantic are such as to require for their application the joint effort of the community at large, kept alive to its interests and duties by the authorities, and men of devotedness to the common welfare. These remedies are (1) Searching for and crushing every potato-beetle wherever found; (2) Frequent visits to the potato-fields, and searching for the eggs deposited on the under-side of the leaves of the potato-vine; and (3) Watching for the presence of the larvæ on the buds and on the leaves of the plant, in order to destroy them by means of Paris green, the only substance yet discovered to be effectually operative on a large scale for the destruction of the insect in its larva state. By these means, and by these means only, the invaded American States, and the Western part of Canada, have been able to secure potato-crops in a measure commensurate with the care and energy bestowed, and by similar means only can the invasion be retarded and lessened in its effects. No measure has been taken in Canada, for reasons given, to prevent the falling or creeping of individual insects on board ships loading in Dominion seaports. There is, however, almost a certainty that the environs of Montreal will be invaded next year, and with that prospect in view, general orders may be given to public officers and *employés* of the ports to look for and destroy any beetles which might be observed on the wharves, on sheds, on packages of goods to be embarked, or on board ships. A general appeal might also be made to all persons having to deal with the shipping for assistance in the execution of such preventive measures. The undersigned respectfully recommends the adoption of such precautions, beyond which he does not see that there is anything within the power of the Canadian Government to do."

CARL JELINEK

DR. CARL JELINEK was born at Brünn, in Moravia, on October 23, 1822. He entered the University of Vienna in 1839 as a student of law, but soon thereafter his attention was turned more exclusively to the mathematical and physical sciences. In 1843 he assisted in the work of the Vienna Observatory, and in 1847 was appointed assistant in the observatory of Prague. It was while assisting in the work of the Vienna Observatory, then under the direction of Kreil, that his interest in exact observations in the fields of meteorology and magnetism was awakened—an interest deep and strong, which soon merged in a life-sacrifice to the furtherance of these sciences.

It is not necessary here to dwell upon his connection with the events of 1848 further than to say that the high moral qualities for which he was in after life so remarkable were even then conspicuous, and that the knowledge he then acquired of men and affairs was an invaluable training for the successful discharge of the duties of the public offices he afterwards filled.

His first important contribution to science was a paper published in 1850 on the construction of self-registering meteorological instruments, an important department of practical science to which he continued to make contributions down to the last. Indeed the last published number of the *Journal* of the Austrian Meteorological Society opens with the last of a series of articles by him on this subject. He was appointed in 1852 Professor of the higher mathematics in the Polytechnic School at Prague. Eleven years afterwards, or in 1863, he returned to Vienna as successor to Kreil, the first director of the Central Institute for Meteorology and Magnetism at Vienna. In this new sphere his remarkable powers of administration and organisation had full scope. The influence of this calm, eager, untiring, and clear-sighted worker and administrator was immediately felt. A new spirit was infused into the machinery of the institute, its resources were increased, connections were formed on all sides with the similar institutes and societies of other countries, and its annual publications were enlarged and improved; and in the course of time not the least important change was effected by the erection of new buildings for the Meteorological Institute on the Hohe Warte—an open commanding position on the outskirts of Vienna—thoroughly equipped with all the instruments required for meteorological and magnetical observation of the most improved construction, and placed in positions which indicate a clear perception of the problems to be investigated and the methods by which the observational data for their solution might be obtained.

On June 14, 1864, he was elected a corresponding, and on August 3, 1866, a full member of the Imperial Academy of Sciences at Vienna. In 1864 he became a member of the Unterrichtsrath, and from 1870 to 1873 acted as secretary of the High Schools for technology and the schools for industry and commerce, and brought to bear on the discharge of these duties the matured results of science, a strong will, and an eagerness and activity that never flagged, which were productive of the best results to the interests of the department he served. His public services were recognised when he retired from the education department in 1873, by having conferred on him the title and rank of Hofrath and the distinction of Knight of the order of the Iron Crown.

It is, however, in meteorology that he appears as an original investigator endowed with an extraordinary capacity for work. In these respects meteorology is perhaps the sternest of the sciences in exacting from those of its votaries who make any permanent contribution to its literature not only keen scientific insight, but also courage to encounter for years, if need be, the constant drudgery of calculations before the end sought can be attained.

That Dr. Jelinek published scarcely any important work on meteorology from 1850 to 1865 need excite no surprise if we keep in view the great and important works on Austrian meteorology which appeared in quick succession from his pen between the years 1865 and 1870. The papers here referred to, about ten in number, several being really voluminous productions, are all of them rich in well-digested tabular matter, which, in relation to the subjects discussed, is of the most satisfying character. The paper on the five-day mean temperatures at Austrian stations from 1848 to 1863 contains 130 closely-printed quarto pages of tables. Among the subjects discussed in these papers are the mean annual and monthly distribution of atmospheric pressure and thunderstorms, and the annual, monthly, five-day, daily, and hourly distribution of temperature over the Austrian Empire; the temperature of Vienna for the ninety years from 1775 to 1864 thus supplying data calculated to throw light on not a few cosmical questions; the cold weather which occurs in May, and the storms of November and December, 1866. An important result of this work is that over the whole of Austria a closely approximate statement can be given as to how far the temperature as observed at any hour of any day of the year is above or below the average. In addition to the above, he wrote his admirable and well-known "Anleitung zu Meteorologischer Beobachtungen," which has already in the present year reached its third edition, and in 1866 established and edited, jointly with Dr. Hann, the *Journal* of the Austrian Meteorological Society, which is published fortnightly, and which, from its liberal and catholic spirit, and the position in science it has attained, stands alone among meteorological publications. In 1865 he succeeded in introducing telegraphic weather reports in Austria. Dr. Jelinek was also Secretary of the Meteorological Society of Austria, and the important services he rendered in connection with the Meteorological Congresses at Leipsig and Vienna are well known.

Thus the Austrian Meteorological Institute, under Dr. Jelinek's management, has not merely made observations and published results, but it has also discharged the functions of a discussing body of a high order. The domain of meteorology in which Dr. Jelinek takes the highest position is that which is concerned with the discussion of averages, taking the term in its widest significance. It is here where his scientific insight appears to the best advantage. We may refer in illustration to the judicious use he makes of the method of differentiation in the discussion of such problems as the normal atmospheric pressure in Austria during the months of the year. He does not commit the mistake of taking different terms of years for different places, according as observations at each place were available, but by the application of the method of differentiation he practically takes the same terms of months and years for all places. In all his writings there is evinced the greatest care to avoid giving expression to any view or speculation unless he had taken the trouble of collecting together all available information that lay in his power bearing on the point in question.

He died, after a lingering illness, on October 19, being thus prematurely cut off at the comparatively early age of our—a man of singularly noble and spotless character, ever on the alert, if we may use the expression, to discover and recognise real work wherever it appeared, and ever ready to offer his help to workers in science, even though he could do so only at the expense of much personal trouble and fatigue. His beneficence was characteristic of the man, being absolutely without ostentation, and his kindly acts were performed as if his left hand knew not what his right was

OUR ASTRONOMICAL COLUMN

DISTANCES OF THE STARS.—We shall here endeavour to present at one view the most reliable results of investigations relating to stellar parallax up to the present time. In making the selection parallaxes less than a tenth of a second of arc are omitted except in the case of the pole-star, for which independent researches have given values closely approximating to this amount. In estimating the "light-years," we adopt Struve's determination of the time occupied by light in traversing the mean distance of the earth from the sun, viz., 8m. 17·78s. (According to Leverrier's last value for the solar parallax, and Clarke's diameter of the earth's equator, this would assign for the velocity of light, 185,360 miles per second, at which rate of travelling it would arrive at the planet Neptune in 4h. 10m., or the breadth of the planetary spaces as at present known would be traversed in less than 8⅓ hours.) By "light-years" is of course to be understood the interval which light would require to pass from the star to the earth at the distances respectively assigned.

The authorities are, for α Centauri, Henderson's value as corrected by Peters, and that of Moesta, the mean; for 61 Cygni, Auwer's mean of his own result and that of Otto Struve; Lalande 21185, Winnecke; β Centauri, Sir Thomas Maclear; μ Cassiopeæ, Otto Struve; Groombridge 34, Auwers; Capella, Otto Struve; Lalande 21258, Krüger; Oeltzen 17415, Krüger; σ Draconis, Brünnow; Sirius, Gyldén from Maclear's observations at the Cape of Good Hope; α Lyræ, Brünnow's mean; 70 Ophiuchi, ; η Cassiopeæ, Otto Struve; Procyon, Auwers; Groombridge 1830, a mean of results of Brünnow, Schlüter, Wichmann, and Otto Struve; and for Polaris, Peters.

Name of Star and Magnitude.	Annual Parallax.	Distance in Solar Distances.	Light-years.
	″		
α Centauri (1 and 4) ...	0·928	222,300	3·5
61 Cygni (5½ and 6) ...	0·553	373,300	5·9
Lalande 21185 (7½) ...	0·501	411,700	6·5
β Centauri (1)	0·470	439,100	6·9
μ Cassiopeæ (5½)	0·342	603,100	9·5
Groombridge 34 (8½) ...	0·307	671,900	10·6
Capella (1)	0·305	676,300	10·7
Lalande 21258 (8½) ...	0·271	761,400	12·0
Oeltzen 17415 (8½) ...	0·247	835,100	
σ Draconis (5)	0·246	838,500	13·2
Sirius (1)	0·193	1,069,000	16·9
α Lyræ (1)	0·180	1,146,000	18·0
70 Ophiuchi (4½)	0·162	1,273,000	20·1
η Cassiopeæ (4½ and 7)	0·154	1,339,000	21·1
Procyon (1)	0·123	1,677,000	26·5
Groombridge 1830 (6½)	0·118	1,748,000	27·6
Polaris (2)	0·091	2,267,000	35·7

In the third column is given the distance of the star from the earth, in mean distances of the earth from the sun, as is usual; it will be seen how greatly the alteration, even of a single unit in the last decimal place of the annual parallax in the preceding column, affects these numbers.

So far as our present knowledge extends, light, travelling at upwards of 185,000 miles per second requires 3½ years to pass from the nearest fixed star to the earth, and it does not reach us from our well-known northern polar star in less than thirty-five years.

THE TOTAL SOLAR ECLIPSES OF 1239, JUNE 3, AND 1241, OCTOBER 6.—Prof. Celoria has published an important memoir on these eclipses, in the *Transactions* of the Royal Institute of Sciences at Milan, vol. xiii. He refers to a note

xii., p. 167, in which, when remarking on his first compu tation of the eclipse of 1239, it was suggested that this phenomenon might deserve further examination in connection with the eclipse of 1241, which had been already calculated by Hansen. The present memoir contains a very careful and complete discussion of the two eclipses, employing Leverrier's tables for the sun, and Hansen's lunar tables, except that the last values for the terms involving the square of the time, given by Hansen in "Darlegung der theoretischen Berechnung der in den Mondtafeln angewandten Störungen," Part 2, are substituted for the values adopted in the tables. The position of the belt of totality in the eclipse of 1241, in its passage across Germany, is very well defined by the statements of contemporary writers, taken chiefly from the great work of Pertz, "Monumenta Germaniæ Historica;" Prof. Schiaparelli had been similarly successful in laying down the actual track of totality across Italy in the eclipse of 1239, from the Records in Muratori's collection of Italian writers. In both cases totality is assumed to have taken place, when there is distinct mention of stars having appeared, which is about the only criterion that has value at these distant times. We shall probably revert to the subject of Prof. Celorai's able memoir.

NOTES

MANY geologists who have visited the Philadelphia Exhibition and seen the geological collections there have been impressed with the importance of having as nearly complete a collection as possible on exhibition, of geological specimens, maps, and sections, in accordance with a previously arranged plan. The International Exhibition to be held at Paris in 1878 will furnish such an occasion, and it is proposed to invite to that end governmental geological surveys, learned societies and private individuals throughout the world, to send to Paris such collections as will make the geological department of that exhibition as complete as possible. In order to take advantage of the collections which may thus be brought together, it is moreover proposed to convoke an International Geological Congress, to be held at Paris at some time during the Exhibition of 1878, and to make that Congress an occasion for considering many disputed problems in geology. In accordance with this plan it is proposed that the Geological department of the International Exhibition of 1878 shall embrace:—1. Collections of crystalline rocks, both crystalline schists and massive or eruptive rocks, including the so-called contact-formations and the results of the local alteration of uncrystalline sediments by eruptive masses. 2. Collections illustrating the fauna and the flora of the Palæozoic and more recent periods. 3. Collections of geological maps, and also of sections and models, especially such as serve to illustrate the laws of mountain structure. In pursuance of the above plan the American Association for the Advancement of Science during its annual meeting at Buffalo, appointed a Committee to carry out this scheme, to which were added the names of Prof. Huxley, Dr. Otto Torell, and Dr. E. H. von Baumhauer. Prof. James Hall was elected chairman, and Dr. T. Sterry Hunt, secretary. It was then resolved to prepare a circular to be printed in English, French, and German, and distributed to geologists throughout the world, asking their co-operation in this great work of an International Geological Exhibition and an International Geological Congress to be held at Paris in 1878; the precise date of the Congress to be subsequently fixed. All those interested in this project are invited to communicate with any one of the following members of the Committee:—Prof. T. H. Huxley, London, England; Dr. Otto Torell, Stockholm, Sweden; Dr. E. H. von Baumhauer, Harlem, Holland; Dr. F. Sterry Hunt, Boston, Mass., U.S.A.

AT a recent meeting of the Literary and Philosophical Society of Manchester, Prof. Osborne Reynolds, in justly animadverting on the large type sensation headings in which some newspapers announced what, in their perversity or ignorance, they called the "failure" of the Arctic expedition, showed that in truth the expedition had been one of the finest achievements ever accomplished. Looked at boldly, it comes to this. Since Hudson's time, more than 200 years ago, Arctic navigators had succeeded in penetrating about sixty or seventy miles of the 540 to be passed before the Pole could be reached. Whereas Capt. Nares has, in one year, carried the British flag some sixty miles nearer, so that nearly one half, and this by far the most difficult half, of the entire results of all expeditions since Hudson's time has been accomplished by the last. And this is not all. Capt. Nares seems to have pursued the journey to its end, at least by that route; and in coming back can say that he did not leave a single uncertainty behind him. So far, therefore, from having been a failure, this has been the most successful expedition ever sent out.

IT is expected that the French Government will ask our Admiralty to establish an Arctic department in the Exhibition of 1878, in which all the relics of English Arctic exploration will be collected and exhibited, as well as all the Parliamentary papers and publications relating to the subject.

M. CHEVREUL was entertained at dinner the other day at the Café Corazza, in the Palais Royal, by eighty *savants* in celebration of the fiftieth anniversary of his professorship and membership of the Academy of Sciences. M. Chevreul, now the oldest member of the Academy of Sciences, is ninety years old, and enjoys perfect health and mental vigour. The most notable instances of academical longevity have been Fontanelle, one of the perpetual secretaries, who died in 1742, aged close on 100 years; M. Biot, who lived ninety-two years, and preserved to the end of his days his mental powers; M. Mathieu, who died March 5, 1875, was also a nonogenarian, and the *Annuaire du Bureau des Longitudes* for 1875 was edited by him. He had succeeded in 1817 Messier, an astronomer, who was an Academician during more than forty years, so that the same seat had only two occupants in a whole century.

A SERIES of lectures is now being given by eminent men of science, explanatory of the instruments in the Loan Collection of Scientific Apparatus at South Kensington. The lectures are free, and working men are invited to attend. The lectures at present arranged for are as follows:—Saturday, November 25, Prof. W. Leith Adams, F.R.S., on "Extinct Animals," as represented by magic lantern slides and specimens in the loan collection. Saturday, December 2, J. S. Gardner on "The Collection of Fossil Leaves." Saturday, December 9, J. Norman Lockyer, F.R.S., on "The Spectroscopes in the Collection." Saturday, December 16, Prof. Huxley, F.R.S., on "The Systematic Teaching of Biology." The lectures will be delivered in the Lecture Theatre of the South Kensington Museum at eight o'clock P.M.

PROF. HUGHES read a paper before the Cambridge Philosophical Society last Monday, in which he criticised the evidence offered to support the view that man existed on the earth during or before the glacial period. He first reviewed several of the older cases which had been put forward, and tried to show that the evidence was always incomplete, or that its trustworthy character disappeared on closer examination. Coming to the two more recent and important instances of human remains or implements being found beneath glacial beds or in beds older than the glacial, Prof. Hughes gave his opinions from personal inspection and acquaintance with the localities. The human fibula found under glacial till in Victoria Cave, Settle, with *Elephas antiquus*, *Rhinoceros leptorhinus*, &c., had been regarded as decisive. Mr. Tiddeman (NATURE, vol. xiv. p.

506) says, "The Settle till is undoubtedly of the age of the ice-sheet." Prof. Hughes said that although the boulder clay at the mouth of the cave had got rather underneath the brow of the hill, yet from intimate knowledge of the physical nature and conditions of the district, which he had himself mapped, he saw no impossibility in the idea of the boulder clay having tumbled from the cliff above during the process of wearing back. Very often the upper limestone was so dissolved as to form pockets into which the boulder clay was let down, and then when an escarpment was disintegrated, he could quite conceive how such a pocket was thrown obliquely against the mouth of the cave in post-glacial times. This had ponded back the water that came into the cave, and necessarily produced a stratified deposit, in which the remains in question were found. With regard to the evidence brought forward by Mr. Skertchley, of the occurrence of palæolithic implements in brick earth beneath the chalky boulder-clay at Thetford, near Brandon, he had visited the locality, and his opinion was that in each case there was a missing link in the proof that the clay beneath which the implements were found was identical with clay at no great distance which was indubitable boulder-clay. In fact, there were many indications of the opposite. Local conditions in denudation, solution of chalk, formation of the valleys, &c., were abundantly present to mask the true state of things. The proof in this case was certainly not cogent; and it must be cogent to be accepted.

We are glad to be able to confirm the report which appeared in our columns a short time ago that the Goldsmiths' Company had promised to contribute 1,000*l*. to the Chemical Society's Research Fund. This sum has now been handed over to the society and raises the amount of the fund already received to 3,050*l*., a sum which we hope will be still further largely increased.

In a communication to the St. Petersburg Society of Naturalists, Prof. Fr. Schmidt sketches the Tertiary formations on the northern shores of the Pacific as follows:—The formation consists of two stages. The Lower is a continental Miocene deposit with coal-seams and numerous plants, the complete description of which will soon appear by Dr. Oswald Heer. This deposit has a very wide extent, having been found in the middle parts of the Amoor basin, on the Sakhalin, in Kamtchatka, Alaska, and on Vancouver Island; and nearly the same rich flora which it contains can be traced as far as the Mackenzie River, Greenland, and Spitzbergen. An immense continent between North-eastern Asia and North-western America must thus have existed at this epoch, and its flora shows the prevalence of a far warmer climate than now, probably like that which the middle parts of the United States now enjoy. The Upper Tertiary stage is a marine Pliocene deposit with numerous remains of molluscs, and it was observed on the Sakhalin Island (but wanting at the same time on the closely-adjacent Siberian continent), in Kamtchatka, on the Aleutian Islands, in Oregon, U.S., and in California. Notwithstanding their varied lithological characteristics, these deposits contain a remarkably uniform fauna. The number of species already described by Prof. Schmidt, on the basis of large collections made during the last thirty years, is eighty, out of which eighteen have no living representatives, six inhabit only the Polar Sea and the Northern Atlantic, and the remaining fifty-six still inhabit the Northern Pacific. Out of the eighteen extinct forms six were already found in the Tertiary of Oregon and California, and one of them (*Nucula ermani*, Girard) will probably prove to be the same as the *N. cobboldiæ*, Sow., of the English Crag. Generally, during the Pliocene epoch, the faunas of the northern parts of the Pacific and the Atlantic were far more alike than now, and it must be supposed that the connection between both oceans through the Polar Sea was far closer than now, a supposition supported also by the close likeness of some forms inhabiting the Pacific and the Atlantic shores of Northern America. Their close likeness, which appears so strange when we learn that they do not now inhabit the Polar Sea, is perfectly explained when we find them in a fossil state in the Pliocene deposits of the far north, as was the case with the *Pholas crispata* and the *Pectunculus pilosus*, which were found fossil, the former on the Northern Dwina and Jenissei, and the second on the Kadiak Island. The fossil fauna of the Arctic regions thus explains the present distribution of forms. Prof. Schmidt expresses the wish that the Pliocene deposits of these regions were thoroughly explored as soon as possible.

At the meeting of October 21 of the Geological Section of the St. Petersburg Society of Naturalists, Prof. Friedrich Schmidt made an interesting communication on the Post-Glacial Period in Esthonia. Starting from the supposition—which he supports in common with Swedish and Finnish geologists—that Esthonia was covered during the Glacial period with an ice-sheet which concealed it with Scandinavia, Finland, Northern Russia, reaching probably the southern slope of the Waldai plateau, Prof. Schmidt proved that after the melting of the ice the country was covered with numerous immense lakes. The land was then submerged by the sea, but only to a small extent, as notwithstanding many years' careful researches, formations with marine fossils have not been found in Esthonia further than 30 kilometres distant from the Gulf of Finland, nor on levels higher than 60 feet above the sea. They are Post-Glacial, containing a fauna which, with very few exceptions, inhabits now the Baltic. After the submergence the land rose to its present height, but this elevation was probably accomplished during pre-historic times. At least, M. Schmidt states, contrary to the assertions of MM. Baer, Hofmann, and others as to the present rising of all the islands of the Gulf of Finland, there was not in Esthonia evidences of the rising of the land during the last four centuries which could be accepted as unmistakable. It may be remarked that the conclusions of Prof. Schmidt as to the small submergence of Esthonia, however contradictory of current opinions are also supported by the circumstance that marine formations were not found in Eastern Sweden above a level of 100–120 feet; and that in Finland the traces of marine clays (with *Cardium edule* and *Tellina balthica*) totally disappear at a level higher than 62 feet. These negative evidences have some weight, both countries having been well explored along some parts of their coasts.

At the meeting of the Literary and Philosophical Society of Manchester, on October 17, Mr. Baxendell drew attention to the paper "On the Protection of Buildings from Lightning," read by Prof. J. Clerk Maxwell at the late meeting of the British Association at Glasgow, and stated that the system of protection recommended by the professor, and which he appears to have regarded as new, was suggested, and its adoption strongly advocated, nearly forty years ago by the late Mr. Sturgeon, whose many valuable contributions to electrical and magnetical science seem to have been strangely overlooked by recent investigators and writers. The paper in which the system was first described was read before the London Electrical Society on March 7, 1838, and an abstract of it was published in the second volume of the "Annals of Electricity." There is, however, one important difference between the two systems. Mr. Sturgeon considered it necessary that the copper sheathing or covering of a protected room or powder magazine should be well connected with the ground; but Prof. Maxwell is reported to have stated that "there would be no need of any earth connection. They might even place a layer of asphalte between the copper floor and the ground, so as to insulate the building." It is obvious, however, Mr. Baxendell states, that if the magazine were struck by lightning, a disruptive discharge through the layer of asphalte would in all probability take place, which might rupture the copper sheathing, and thus ignite the contents of the magazine; but by the adoption of Mr. Sturgeon's plan an accident of this kind could not occur.

Her Majesty has commanded that instructions be given to the Master of the Mint to prepare a die and cast a sufficient number of medals commemorative of the Arctic Expedition. These are to be distributed amongst the officers and crews of the *Alert*, the *Discovery*, and the *Pandora*. The Lord Mayor, Sir Thomas White, is to give a dinner to the crews of the *Alert* and *Discovery* at the Mansion House, on the evening of December 5. The Lord Mayor intends to invite the officers of the expedition to a banquet a few days later, probably December 8. The inhabitants of Portsmouth intend to entertain the crews of the *Alert*, *Discovery*, and *Pandora* at a dinner on the 30th inst.

Mr. R. J. Friswell has resigned the honorary secretaryship of the Photographic Society.

The Ethnographical Museum of Berlin has lately received several valuable additions, viz., the objects acquired by Dr. Lenz during the German-African Expedition. They represent tribes from the West Coast of Africa hitherto little known, and consist of various wooden weapons, domestic implements and musical instruments. Very shortly the excellent collections of the celebrated African traveller, Dr. Nachtigal, are also to be exhibited at the museum. Some of these come from tribes which Dr. Nachtigal was the first European to see. Much inconvenience is felt at the museum through want of space, and particularly so with reference to some American curiosities sent for exhibition by Prof Bastian.

St. John's College, Cambridge, offers for competition an exhibition of 50*l.* per annum, for proficiency in Natural Science. The examination will commence on Saturday, April 7, and will be in chemistry, including practical work in the laboratory; Physics, viz., Electricity, Heat, and Light; and in Physiology Candidates will also have the option of being examined in Geology, Comparative Anatomy, and Botany, provided they give notice of the subjects in which they desire to be examined four weeks prior to the examination. No candidate will be examined in more than three of these six subjects, whereof one at least must be chosen from the former group. It is the wish of the master and seniors that excellence in some one department should be specially regarded by the candidates. Names should be sent to one of the tutors at least fourteen days before the examination.

A chair of Physical Astronomy has been created in the Faculty of Sciences at Lyons.

How rapidly an interest in prehistoric researches is spreading among the educated classes in Germany is seen in the progress of the Anthropological Society of Munich. It was constituted in 1870 as a branch of the German Anthropological Society, founded only three weeks before it. It began with thirty-five members and now numbers 300.

The present efforts of the German Anthropological Society are directed towards the preliminary preparations for an Anthropological and Primitive History of Germany; by means of a territorial division of labour, extremely important data have already been obtained. Contributions on particular points are appearing in the *Correspondenzblatt* of the German Anthropological Society, the *Archiv für Anthropologie*, and the Berlin *Zeitschrift für Ethnographie*. Meantime, at the Anthropological Meeting held in Munich last year, a plan was formed by a number of Anthropologists, in reference to the astonishing richness of the prehistoric discoveries in Bavaria, for the advancement of German Anthropology, by the establishment of an organ for the publication of the complete results which have been obtained in reference to Bavaria. The accomplishment of this scheme has now commenced with the publication of a part of the *Beiträge zur Anthropologie und Urgeschichte Bayerns*, an organ of the Munich Society of Anthropology. This part contains a monograph on the "Lake Dwellings in the Würm See," by S. v. Schab, who has thoroughly explained this prehistoric dwelling-place, and collected and arranged the rich finds. The most important of the latter are shown in seventeen lithographic plates, partly coloured, with maps, plans, &c.

The *Daily News* Alexandria correspondent sends to that paper, November 21, some particulars of the life and work of an African explorer who has been quietly doing good service for many years. This is Signor Piaggia, who went to Tunis first in 1851 as a gardener, and there and in Alexandria saved money for years, with which he went up to Khartoum. From then until now he has made several important journeys; to the country of the "Kicks," the territory of the Niam-Niams, where he became a great favourite, and stayed more than two years, the Bogos territory on the borders of Abyssinia with the Marquis Antinori, into Cerada, south-east of Lake Tzana, which he explored minutely. Latterly, after accompanying Gessi for some distance, he has been in the districts of Mroli and Mtesa, and made a thorough exploration of the Lake Capechii. From all his journeys he has brought back large collections of objects of all kinds, which, it is believed, are now for sale.

The *Moniteur de l'Algérie* states that from November 8 a violent sirocco, or wind from the desert, was felt in Algeria for several days. This accounts for the unusual elevation of temperature in Algeria.

The exhibition of fossils, paintings, plants, and other objects illustrative of the mountain limestone in the Manchester Aquarium, was closed on Monday, having been open to the public a little more than a week. The exhibition has been in every way successful.

Further details received regarding the cyclone of October 31 prove it to have been one of the most terrible calamities on record. Estimates based on official returns from each police section put the loss of life in the districts of Backergunge, Noakholly, and Chittagong at not less than 215,000. Three large islands—Dakhin Shahabazpore, Hattiah, and Sundeep—and numerous small islands were entirely submerged by the storm wave, and also the mainland for some five or six miles inland. These islands are all situated in or near the estuary of the Meghna, a river formed by the confluence of the Ganges and Brahmapootra rivers. Up to 11 P.M. on the night of the catastrophe there were no signs of danger, but before midnight the storm wave swept over the islands to a depth in places of 20 feet, surprising the people in their beds. The country is perfectly flat, and, therefore, trees were the only secure range. Almost every one perished who failed in reaching trees. A strange fact about the disaster is that in Dakhin Shahabazpore and Hattiah most of the damage was done by the storm wave from the north sweeping down the Meghna. Several theories, the *Times* Calcutta correspondent states, have been started to account for this. One is that the cyclone, forming in the bay, struck the shore first near Chittagong, and went north for some distance, and then turned southward again. Another is that the wind blew back the waters of the Meghna, which rebounded with terrific force when the pressure relaxed. A third supposition is that there were two parallel storms with a centre of calm between them. The first or third theory seems most probable, as in Sundeep and Chittagong the destruction came from the south.

Mr. Henry Meiggs, the well-known American railroad contractor and engineer, whose efforts in connection with the establishment of railroads in Peru are so well known and appreciated, has recently furnished the means to M. Bur, a

French ethnologist, for carrying on some explorations in the vicinity of Tiahuanuco, in Bolivia, a region which abounds in objects of archæological interest. Mr. Meiggs has arranged that a full series of these objects shall be presented to the U.S. National Museum.

A VALUABLE entomological collection has been presented to the Oxford University Museum by Mrs. Tylden, the relict of the late Rev. W. Tylden, formerly of Balliol College. The collection numbers 23,518 specimens, arranged in cabinets.

PROF. PALMIERI, Director of the Observatory on Mount Vesuvius, has been made an Italian Senator.

A DESPATCH received at Rome from Aden, November 19, states that the Italian African Expedition has arrived in Shoa.

THE Government Resident at Somerset has telegraphed to the Colonial Secretary that Messrs. D'Albertis, Hargrave, and party have returned safely from their expedition to the Fly River. They ascended the country a distance of 350 miles above the spot reached by the expedition party of last year. They were unable to communicate in any way with the natives who were very numerous and hostile.

A SIXTH edition of Prof. Page's well-known "Advanced Text-Book of Geology" has been published. The work has been enlarged "to embrace whatever is new and important in the science, to afford space for additional illustration, and to combine, as far as possible, the principles with the deductions of geology."

WE have on our table the following books :—Preliminary "Report on the Forests of Pegu," by Sulpice Kurz (Calcutta). "The Aquarium," J. E. Taylor (Hardwicke and Bogue). "Spiritualism and Animal Magnetism," Dr. Zerffi (Hardwicke and Bogue). "The Theory of Colour," Dr. W. von Bezold (Trübner). "The Art of Retouching," Burrows and Colton (Marion). "Science in Sport made Philosophy in Earnest," by Robert Routledge (George Routledge and Sons). The ninth edition of "Kirke's Physiology," edited by Morrant Baker (John Murray). "Between the Danube and the Black Sea," H. C. Barkley, C.E. (John Murray). The fourth edition of Wanklyn's "Water Analysis" (Trübner). "Demonstrations of Microscopic Analysis," Harley and Brown (Longmans). "Mushrooms and Toadstools," Worthington G. Smith (Hardwicke and Bogue). "Geological Observations," Charles Darwin, F.R.S. (Smith, Elder, and Co.). "Lessons in Electricity," John Tyndall, F.R.S. (Longmans). "Our Birds of Prey," The Raptores of Canada, H. G. Vennor (Sampson Low and Co.).

THE additions to the Zoological Society's Gardens during the past week include two Prussian Carp (*Carassius vulgaris*), European, presented by Lord Arthur Russell, F.Z.S. ; a Bubaline Antelope (*Alcelaphus bubalinus*), an Addax Antelope (*Addax naso-maculatus*) from North Africa, a Buff-breasted Partridge (*Ptilopachys ventralis*) from West Africa, four Brazilian Cormorants (*Phalacrocorax brasiliensis*) from Brazil, purchased ; a Macaque Monkey (*Macacus cynomolgus*) from India, a Chilian Sea Eagle (*Geranoaëtus aguia*) from South America, deposited ; a Hairy-rumped Agouti (*Dasyprocta prymnolopha*), born in the Gardens.

SCIENTIFIC SERIALS

Schriften der physikalisch-oekonomischen Gesellschaft zu Königsberg (1875, 1 and 2).—These parts, amongst a number of smaller papers and notes, contain the following more important treatises: —On the determinations of temperature in the soil at different depths at the station at Königsberg, by Prof. E. Dorn.—Observations on the genera of *Nematidæ*, by C. G. A. Brischke and Prof. Dr. G. Zaddach. This paper occupies more than half of Part 1.—On the temperature in the interior of animal bodies, by Dr. Adamkiewicz.—On a new species of Algæ, *Merismopedium Reitenbachii*, Casp., by Prof. Caspary.—On the different forms of the stigmatic disc of *Nuphar luteum*, Sm., by the same.—On the latest investigations made by M. Lassaulx on earthquakes, by O. Tischler.—On the so-called "Moosbrüche," specially on the "Zehlaubruch," near Tapiau, by Herr Stiemer.—On the courses of rivers," &c., in the North German plains during the Diluvial period, by Prof. Berendt.—On one of Euler's geometrical problems, by Dr. Saalschütz.—On the courses of rivers in the province of Prussia, by Herr Stiemer.—On the Colorado beetle, by Dr. Schiefferdecker.—On reflectors, by Dr. Berthold. —On Gore's rotating ball, by Herr Momber.—On the artificial production of colours from the white of eggs, by Dr. Adamkiewicz.—On Phylloxera, by Dr. Benecke.—On the oscillations of *terra firma*, by Dr. A. Jentzsch.—New list of Prussian beetles (fourth paper), by Dr. Lentz. The author makes the total of different species to the number of 3,216 !—On old Prussian "Kjökken Möddings" at the coast of the "Frische Haff," by Prof. Berendt.—On the conception of value in the different theories of the same, by Adolf Samter.—On the power of accommodation amongst plants and insects, by Dr. G. Czwalina.—On an erratic block-limestone found near Tilsit, by Dr. Friederici.—On salicylic acid, by Prof. Samuel.—Archæological researches on the "Kurische Nehrung," by O. Tischler.—On an alleged proof of the early existence of man in Europe, by Dr. Jentzsch.—On an unusually large fungus, *Agaricus suffructicosus*, by Prof. Caspary.—The Appendix contains the report sent by the Society to the Provincial Landtag on its geognostical researches in the province of Prussia.—The parts further contain a memoir of the late Prof. Argelander, of Bonn, by Dr. Luther.

SOCIETIES AND ACADEMIES

LONDON

Mathematical Society, November 9.—Prof. H. J. S. Smith, F.R.S., president, in the chair.—Mr. J. W. L. Glaisher communicated a note on certain identical differential relations.—Mr. Tucker read parts of papers by Mr. Spottiswoode on curves having four-point contact with a triply-infinite pencil of curves, and by Mr. E. B. Elliott on some classes of multiple definite integrals.—In a paper published in the *Mathematische Annalen* (vol. iii. p. 459) Brill has investigated the case of curves having three-point contact with a doubly infinite pencil of curves ; and in the same journal (vol. x. p. 221) H. Krey, of Kiel, has applied a method, similar to that of Brill, to the next step in the problem proposed in Mr. Spottiswoode's paper. He does not, however, appear to have succeeded in completely eliminating the differentials which occur in the process ; and in that respect his solution is incomplete. Some formulæ used in Mr. Spottiswoode's paper on the contact of curves and surfaces, and in particular in that on the sextatic points of a plain curve (*Phil. Trans.*, 1865, p. 657), prove to be directly applicable to the question. An application of them to Brill's problem will be found in a paper in the *Comptes Rendus* (1876).

Astronomical Society, November 10.—Mr. Huggins, president, in the chair.—The Astronomer-Royal gave a short account of the proceedings of the Royal Observatory during the recess, describing the lunar and physical observations which had been assiduously prosecuted and the state of the calculations for his new lunar theory.—A paper by Prof. Langley, of the Allegany Observatory, Pennsylvania, on the measurements of the direct effects of sun-spots on terrestrial climates was read. Prof. Langley has made experiments to determine the difference in the amount of heat radiated from the centre of a sun-spot and from an equal area of penumbra and photosphere. Combining these results with the amount of the sun-spot area given as existing during a period of maximum of sun-spot frequency in the tables of Messrs. De la Rue, Stewart, and Lœwy, he calculated that the mean terrestrial temperature due to solar radiation at a period of sun-spot minimum would be something between three-tenths and one-twentieth of 1° C. greater than at a period of sun-spot maximum. The Astronomer-Royal pointed out that the observations of underground temperature made at the observatories at Paris, Edinburgh, and Greenwich showed differences in the mean annual temperature of the surface soil which amounted to as much as 6° F. An examination of the temperatures at different depths showed that the differences of surface temperature had their cause in something external to the earth, but he had not found that the differences of mean surface temperature coincided with the variations in the amount of the English serial crop as given by the Board of Trade returns or with the periods of sun-spots maxima. Mr. De la Rue said that it did not follow that the amount of solar radiation would necessarily vary inversely as the sun-spot area, for at a period of maximum sun-spot area it was possible that the radiation from the photosphere might be increased to such an extent as wholly to counteract the difference caused by the decrease in the apparent area of the photosphere. He further remarked that the numbers given in his papers in conjunction with Messrs. Balfour Stewart and Lœwy must not now be relied upon, as some serious errors had been discovered which he was now endeavouring to put straight by a re-investigation of the whole subject.—Mr. Penrose read a paper entitled "An Endeavour to simplify the Method of making the Correction for the Spheroidal Figure of the Earth in Lunar Observations, and particularly with Reference to its Effect upon the Lunar Distance."—Mr. Christie described some observations which he had made with a polarising photometer upon the relative brightness of different parts of the disc of Venus. He had found that when the disc of Venus was gibbous, the last part of the disc to disappear, as its brightness was decreased by rotating his photometer, was a sausage-shaped patch, the convex edge of which was found to be distinctly within the limb of the planet. He thought that his observations supported Mr. Brett's theory as to specula reflection from the surface of Venus.

Linnean Society, November 2.—Prof. Allman, president, in the chair.—In exhibiting a live specimen of the Norwegian Lemming, the survivor of seven at starting, Mr. Duppa Crotch called attention to charts he had made showing the nature of the ground traversed in two instances in which he himself had witnessed the westerly migration of this singular little rodent.—Mr. G. Bentham, vice-president, read a paper on the distribution of the Monocotyledonous order into primary groups, more especially in reference to the Australian flora, with notes on some points of terminology.—Dr. Francis Day drew attention to examinations he had made on some Irish sticklebacks (*Gasterostei*). These had led him to doubt the conclusions arrived by M. Sauvage (*Nouv. Archiv. d. Mus.*, 1874), as to the propriety of dividing the family into subgenera and some seventeen species. Dr. Day has noticed such abnormal variations in the presence and absence of ventral fin and spines in specimens of the three-spined and ten-spined sticklebacks as cause him to believe these appendages to be a very imperfect diagnostic and specific character. Nay more, as certain other Acanthopterygians have been generically divided by such features, it is questionable whether further observations may lead to considerable necessary revision of the families. He is of opinion, moreover, that the spinal armature of at least the *Gasterostei* has an increment in the ratio of their proximity and access to a maritime habitat.—Mr. H. W. Bates communicated a paper by Mr. D. Sharp on the respiratory function of the Carnivorous Water Beetles (*Dytiscidæ*). Experiments made by the author on numerous species show that there are wide differences in the length of time they spend submerged and on the surface for breathing exposure. For example, the *Pelobius Hermanni* remains under water in a ratio of 375 to 1 of air exposure; whereas *Dytiscus marginalis*, a more highly developed form, has a corresponding ratio of about 12 to 1. Most specimens of the group are more active by night than by day. The *P. Hermanni* and *Hydrovatus clypealis* he regards as much less developed, and adapted for moving through the water than our indigenous water-beetles; and therefore, along with the American Amphizoa, appear to him to represent the most rudimentary and primitive of existing forms of the Dytiscidæ.—Prof. Dickie gave a supplemental notice of Marine Algæ obtained in the *Challenger* Expedition. Of some fifty species one only is new.—A description of *Thaumantis pseudaliris* and *Amesia pexifascia*, two new Lepidopterous forms from Malacca, by Mr. A. Butler, was taken as read.—The same author also had a communication on the genus *Euptychia*, a revision, with the addition of twelve new species being made; a case of these butterflies was exhibited in illustration of his paper.—A second communication, by Mr. D. Sharp, referred to new species of beetles (*Scarabæidæ*) from Central America; these had been captured by Mr. Belt, chiefly in the neighbourhood of Chontales.—Mr. A. Peckover exhibited and made a few remarks on two skins of the young of the Madagascar insectivore, *Hemicentetes nigriceps*, Günth., and on a series of insects from the same island, collected by Mr. A. Kingdon, near Antananarivo.—Mr. E. D. Crespigny showed a specimen of the Umbelliferous plant, *Tordylium maximum*, L., obtained near Tilbury Fort, a locality where it had disappeared for a considerable length of time.

Chemical Society, November 16.—Prof. Abel, F.R.S., president, in the chair.—A paper on barwood, by the late Prof. Anderson, was read by the Secretary, describing the method of preparing *baphuin* from it, and also some of the educts obtained by the action of various reagents.—The second communication was on the alkaloids of the aconites, Part I. on the crystallisable alkaloids contained in *Aconitum napellus*, by Dr. C. R. A. Wright. The author finds that the alkaloids from *A. ferox*, which he calls *pseudanicotine*, $C_{36}H_{49}NO_{11}$, differs both in properties and in composition from *aconitine*, $C_{33}H_{43}NO_{12}$, the crystalline alkaloid of *A. napella*. In one instance, however, he obtained from the root of the latter a perfectly distinct bitter crystalline alkaloid, *picroconinite*, possessing scarcely any toxic power; whether this is an alteration product of aconitine or not remains at present undetermined.—Mr. G. S. Johnson then read a paper on potassium triiodide, a crystalline compound obtained on saturating a saturated solution of potassic iodide with iodine, and slowly evaporating the solution over sulphuric acid. It forms prismatic or tabular crystals having an appearance very similar to that of iodine.—The last communication was by Mr. T. S. D. Humpidge, on the coal-gas of the metropolis. He has carefully analysed and determined the illuminating power of different samples, and comes to the conclusion that the gas at present supplied is but little if any better than it was twenty-five years ago, the actual increase in illuminating power being due to the use of improved burners.

Physical Society, Nov. 4.—Prof. G. C. Foster, president, in the chair.—The following candidates were elected members of the society:—Warren de La Rue, D.C.L., F.R.S., and W. H. Preece.—Dr. Guthrie read two letters which he had received from Dr. Forel, in continuation of a communication which he made to the Society on May 27 last, in reference to the "Seiches" or periodic oscillations which take place in the Swiss lakes, and on which he has recently made an elaborate series of observations. Since his communication he has found in a pamphlet by Dr. J. R. Mérian, published in 1828, a formula which is strictly applicable to the phenomena under consideration. If t be the duration of half an oscillation, h the depth of the lake, and l its length, $t = \sqrt{\frac{\pi l}{g}} \left\{ \frac{e^{\frac{\pi h}{l}} + e^{-\frac{\pi h}{l}}}{e^{\frac{\pi h}{l}} - e^{-\frac{\pi h}{l}}} \right\}^{\frac{1}{2}}$. Considering that probably this formula will be applicable to lakes of irregular depth if h be the mean depth, he has applied it to several lakes, and the following are some of his results. In the case of transverse seiches on Lake Leman, the formula gives 216 metres as a mean depth, and 334 metres is the greatest known depth. With a longitudinal oscillation, the mean depth is found to be 130 metres. In the case of Lake Wallenstadt, the formula having shown the mean depth to be somewhat greater than the generally accepted greatest depth, Prof. Forel took a number of fresh soundings, and found a great basin of comparatively even bottom and of such a depth as to render probable the mean depth given by the formula.—Mr. O. J. Lodge suggested that the formula would be rendered more simple by using the hyperbolic function. It would then become $t = \pi \sqrt{\frac{l}{g}}\ \text{Coth}^{\frac{1}{2}} \frac{\pi h}{l}$. Mr. Lodge also indicated the curve which this equation represents.—Dr. Stone exhibited some diffraction gratings on glass and metal, ruled for him by Mr. W. Clark, of Windsor Terrace, Lower Norwood. The majority of them were close spirals about 1,000 to the inch, which, when held between the eye and a distant lime-light, exhibited circular spectra of great brilliancy. The slight difference between the spiral and true circles appeared to exercise no appreciable effect on the result. The metal gratings were of linear form, 1,000 lines to the inch, intended for use by reflection in a spectroscope. The spectra thus obtained were of much greater brilliancy than those ordinarily obtained by refraction, and presented obvious advantages for examining the ultra-violet rays. He explained the mechanical difficulties which had been surmounted in their manufacture together with the manner in which the diamond cutters are prepared. The metals hitherto employed, namely, cast-steel and German silver, are objectionable, and Dr. Stone proposes, on the suggestion of Prof. McLeod, to employ speculum metal, and will report the result of the experiments more fully at a subsequent meeting.—Dr. Guthrie then briefly described some experiments which he has made to determine the effect of a crystalloid on a colloid when in the presence of water. Mr. Graham, in his classical researches, made numerous experiments with a salt on one side of a colloid membrane and water on the other, and Dr. Guthrie thought it might be well to determine what action, if any, takes place when a salt is added to a solution of a colloid such as size. Two or three lumps of rock salt were added to a jelly of size, and the whole hermetically sealed in a glass tube. The colloid parted with its water readily, a saturated solution of the salt was obtained, and the size became perfectly white and opaque, having undergone a structural change. Experiments were also made employing a more hygrometric salt, such as chloride of calcium.—Mr. W. C. Roberts pointed out that a jelly containing 5 per cent. of silicic acid readily parts with water to sulphuric acid, and dries into a hard glass like hydrate of silica. He asked whether this might be considered as analogous to the action of salt on size, or whether the strong affinity between the acid and water removed it to another class of action. Dr. Guthrie thought it might be possible to establish the existence of a point at which the jelly did not give up its water to the hygrometric substance. He also pointed out the analogy between a jelly and a mass of small bags filled with liquid.

Entomological Society, November 1.—Prof. Westwood, president, in the chair.—Mr. F. Smith exhibited some remarkable specimens of thorns from Natal and Brazil, which had been taken possession of by certain species of *Cryptoceridæ* for the construction of their nests. Some of the thorns were as much as 3 inches in length.—Prof. Westwood mentioned an instance of the hairs of a larva of *Lasiocampa rubi* having caused considerable irritation of the skin, and that the irritation was complained of by his correspondent for a week afterwards.—The Professor exhibited a singular Coleopterous larva from Zanzibar, of a flattened, ovate form and a steel-blue colour, with two points at the extremity of the body, and with long, clavate antennæ. The head bore some resemblance to that of the dipterous genus *Diopsis*. He also exhibited a specimen of the butterfly, *Hesperia sylvanus*, received from the Rev. Mr. Higgins, of Liverpool, having the pollinaria, apparently of an Orchid, attached to the base of the tongue. Also an Orchid bulb purchased by Mr. Hewitson with a collection of roots from Ecuador, which was found to contain nine living specimens of cockroaches, comprising six different species, viz., *Blatta orientalis*, *Americana*, *cinerea*, *Maderæ*, and two others unknown to him, some being of considerable size.—Mr. Dunning read a "Note on *Acentropus*," in which he remarked on Heer Ritsema's Second Supplement to his Historical Review of the genus, published in the *Transactions* of the Entomological Society of the Netherlands, in which that author tried to prove that two distinct species existed, of which one (*A. niveus*, Oliv. = *A. Garnonsii*, Curt.) has a female with rudimentary wings, and the other (*A. latipennis*, Möschl. = *Zancle Hansoni*, Ste.), has a female with normally developed wings; whereas, Mr. Dunning argued that the facts, as stated by Heer Ritsema, did not in any way prove the duality, but were quite consistent with the unity of the species.

Institution of Civil Engineers, November 14.—Mr. George Robert Stephenson, president, in the chair.—The paper read was on the Japan lights, by Mr. R. H. Brunton.

PARIS

Academy of Sciences, November 13.—Vice-Admiral Paris in the chair.—The following papers were read:—Theorems relative to systems of three segments making a constant length, by M. Chasles.—Note on the recent progress of phylloxera in the departments of the two Charentes, by M. Bouilland.—Continuation of observations of eclipses of Jupiter's satellites at the Observatory of Toulouse, by M. Tisserand. For eclipses of the first satellite little seemed to be gained by using larger instruments; for those of the second and third the difference was greater.—M. Milne-Edwards presented the first part of tome xii. of his work on comparative physiology and anatomy of men and animals. It treats of audition and sight.—Report on a memoir of M. Fouqué, "Mineralogical and geological researches on the lavas and dykes of Thera" (island of Santorin group). These lavas contain two, and often three triclinic felspars (some say volcanic rocks never contain more than one); albite predominates among the small crystals; labradorite or anorthite among the large. These anorthite lavas (hitherto thought exceptional) form forty-one of the dykes of Thera. M. Fouqué shows, from experiments, that a lava fused and suddenly cooled is quite as crystalline as when it has solidified slowly; crystals are formed before ejection from the ground. Contrary to M. Tschermak, who would eliminate from the catalogue of mineralogical species all triclinic felspars except albite and anorthite, M. Fouqué shows reason for retaining oligoclase and labradorite. Tridymite, a variety of crystallised silicon, is found in the lavas in form of thin hexagonal imbricated plates; M. Fouqué regards it as a posterior formation to the other elements, and as having arisen at a high temperature under the influence of imprisoned droplets of water, when the surrounding rock was liquid or viscous. The report speaks highly of the value of this memoir.—Researches on the brachistochrome of a heavy body, with regard to passive resistances, by M. Haton de la Goupillière.—On the characteristics of systems of conics and surfaces of the second order, by M. Halphen.—M. François recommended, against phylloxera, the vitriolic water from the mines of pyrites of Sainbel.—Observations relative to the general theory of trombes, by M. Virlet d'Aoust. He describes some dust whirlwinds observed on the Mexican plateaux.—Determination, by the method of analytic correspondence, of the envelope-surface of a surface whose equation contains n parametres connected together only by $n-2$ relations, by M. Saltel.—Influence of temperature on magnetisation, by M. Gaugain. The value of the temporary variation varies considerably from one bar to another. To determine the influence of temperature this should be kept invariable throughout an experiment; the author describes how he accomplished this. With a bar susceptible of considerable temporary variation, the magnetism developed at 300° is weaker than at ordinary temperature, but in the opposite case it is stronger.—On the hydrates of sulphate of copper, by M. Magnier de la Source.—On margaric chloride and its derivatives, by M. Villiers.—Researches on quercite, by M. Prunier. He considers quercite to form a transition between the fatty series and the aromatic series.—On angelic acid, by M. Demarçay. He verifies his former experimental results against some contradiction of them by M. Fittig in the Berlin Chemical Society.—Physiological experiments on the functions of the nervous system of Echinida, by M. Fredericq. The cords described as the nervous system are the means by which harmony of movements is established. Facts seem also to favour the existence of a nervous plexus situated in the thickness of the external tegument.—On the mobile state of *Podophrya fixa*, by M. Maupas. This, he says, hardly merits its name; it is more mobile and vagabond than known Acinetinians, and is an intermediate type between suctorial infusoria and ciliated infusoria, properly so called. He describes in detail the changes which take place in it during its mobile period.—On the existence of asparagine in sweet almonds, by M. Portes.—On the influence of leaves and floral branches on the nature and quantity of sugar contained in the scape of agave, by M. Balland. Both leaves and flowers have an incontestable *rôle* in the formation of sugar.—On a meteoric iron very rich in nickel, found in the province of Santa Catharina (Brazil), by MM. Guignet and Ozorio de Almeida; iron 64 per cent., nickel 36. It appears to belong to the terrestrial rocks. M. Daubrée remarked that a careful examination of all that region was very desirable.—Chemical composition of the water of the Bay of Rio de Janeiro, by MM. Guignet and Teller. It contains considerable quantities of silica and alumina (9·5 and 7·5 gr. respectively, per cubic metre). This is from decomposition of the gneiss and granite rocks under friction of the water.

FERRIER ON THE BRAIN

The Functions of the Brain. By David Ferrier, M.D., F.R.S. With numerous Illustrations. (London: Smith, Elder, and Co., 1876.)

II.

SINCE it is certain that the movement of a limb may be occasioned by an idea, an emotion, or a sensation, and also by the reflex of an external stimulation; since, moreover, it is certain that such a movement may be arrested by an idea or emotion; and since there is good ground for the hypothesis that the cerebral hemispheres are, if not the sole agents, at any rate indispensable accessories in the production of ideas and emotions, we have every right to conclude that the hemispheres play a part in the normal production of many movements; and that ideas and cerebral processes are the subjective and objective aspects of one and the same effect. But experiment proves that many, if not all, these movements can be executed in the absence of the hemispheres, therefore the hemispheres are not *indispensable* but *accessory* factors. This leads to the question, What part do they play? And this again to the questions, Are all cerebral processes or only some of them, ideas emotions, and sensations, the others being simply molecular movements which propagate their excitation to centres of muscular innervation?

I understand the Hitzig-Ferrier view to be this: One set of cerebral processes, having their centres or terminal stations in a limited region of the cortex, are sensational, emotional, and ideal; another set, having also all their centres or terminal stations in a limited region of the cortex, are motor. I am not quite sure that this representation is exact, for in both writers there is absence of explicit definition. But this much at least may be taken as exact, that they profess to have discovered limited areas of sensory and motor stimulation, and within these areas limited spots for particular sensations and particular movements. The interpretation must, of course, rest on a basis of fact, yet the facts observed may be accepted without forcing acceptance of the interpretation. There is general agreement on the facts with great want of agreement as to the conclusions. I have already suggested that the discoveries of Hitzig and Ferrier are of great importance; but only as finger-posts for anatomists seeking the pathways of stimulation, not as inductive stations for deductive inferences. All we can say at present is that electrical stimulation of certain spots is followed by certain movements; but *how* the stimulation reaches the motor nerves is as dark as before.

Thus far, therefore, the part played by the cerebral process is only recognisable as an incitation; it certainly does not effect the movements, it only incites the motor organs. And *thus far* it is on a level with *peripheral* incitations, such as the incitation of laughter by tickling the sole of the foot; or of vomiting by tickling the fauces. Laughter is a function of a complex apparatus, and this apparatus may be stimulated in very different ways from very different starting-points—an idea, a sight, or a touch. Vomiting, again, follows from a blow on the head, acidity in the stomach, a disgusting sight, a smell, or a tickling of the throat. No one considers the sole of the foot and the fauces to be centres or terminal stations for the functions of laughter and vomiting. Why, then, when we see movements of the limbs, the eyes, or the tail following stimulation of the cerebral cortex, are we to conclude these movements to have their centres in the cortex? The foot may be removed or the sole rendered insensible, yet still laughter will be stimulated by ideas, sights, &c., as before. In like manner the spot of the cerebral cortex may be removed or destroyed, yet still the limbs will move as before. Nay, not only the cortical spots, but the whole hemisphere may be removed, and still the limbs will move as before.

For anatomical purposes we make a wide distinction between grey matter and white, and a still wider distinction between central and peripheral nerve-substance. Physiologically such distinctions are, I conceive, erroneous, the whole nervous system being one. But the distinction between a centre—*i.e.*, a place (*to* which stimulations are carried, and *from* which motor impulses issue—and a peripheral region where stimulations begin or end—is both a physiological and an anatomical division usefully maintained. According to this definition of a centre, we may doubt whether the cortex of the cerebrum has any claim to be called a centre, or group of centres, *whether, in fact, it is not a peripheral region*, the processes of stimulation in it being of the same order as the processeses of stimulation in the skin, or mucous membranes, *i.e.*, simply those of peripheral incitation.

This is the paradox to which allusion was made at the close of my former article. As it would occupy too much space for development here, and as I have worked it out in a volume now at press, I merely suggest it for speculative readers, and pass on to Dr. Ferrier's book.

First as to his facts. It has been urged against his localisations that he has employed a too powerful current. On this subject I have no right to an opinion, but incline to accept his reply as satisfactory; though one must not overlook the fact remarked by Carville and Duret, that very different movements may be occasioned by the stimulation of one and the same spot according to intensity of the current—a fact analogous to what is observed in stimulations of the skin. It has been urged by Hitzig, and also by Braun (Eckhard's "Beiträge," vii., 133, 137), that in Dr. Ferrier's experiments the same movements follow stimulation of different spots, even when these spots are situated in the different regions recognised as excitable and non-excitable. The objection is not only triumphantly answered by Dr. Ferrier, but is answered by the introduction of an idea which is of great significance:—"The mere fact," he says, "that movements result from stimulation of a given part of the hemisphere does not necessarily imply that the same is a motor centre in the proper sense of the term. It will afterwards be shown that the movements which result from stimulation of the regions in question are expressive of sensation, and that the character of the movements furnishes an important index to the nature of the sensation" (p. 147; compare also p. 163).

As an answer to his critics this seems conclusive. But does it not throw a serious difficulty in the way of his hypothesis? If, as he luminously suggests elsewhere, "the sensations accompanying muscular action being repeated as often as the muscular action itself, the organic nexus between the motor and tactile centres becomes so welded, that this sensori-motor cohesion enters like a compound chemical radical as a simple factor into every association which motor centres can form with other motor centres and with sensory centres in general" (p. 268); then surely this, while it satisfactorily accounts for the motions following excitation of sensory regions, leaves unexplained the facts of other such excitations *not* being followed by motions (comp. p. 231), and raises the question whether all motions are not due to sensory excitation? On the first point let us ask why the optic thalami—said by him to be sensory centres—do not respond by motor manifestations when stimulated? He regards this "as sufficient of itself to dispose at once of the views of those who would attribute motor functions to these ganglia. The fact that lesions of the optic thalami cause paralysis of motion proves nothing regarding the real functional significance of these ganglia" (p. 239). Agreed; but then why does he not equally conclude that absence of paralysis of motion, when the corpora striata are destroyed, disproves the motor function he assigns to these ganglia, especially since direct stimulation of these ganglia does not produce motions?

Then, again, if sensorial excitations produce movements by playing upon the motor centres, why not adopt the view which regards all cerebral excitation as sensorial? The hypothesis of motor centres in the cortex would thus be resolved into the fact that particular sensations excite particular movements; and the localisation of spots on the cortex would be no more than analogous localisations on the skin—the sensation excited by tickling the sole of the foot, causing different movements from those caused by the same stimulus applied to the heel or instep.

Dr. Ferrier has explicitly declared that "there is no reason to suppose that one part of the brain is excitable and another not. The question is how the stimulation manifests itself" (p. 130). This is in accordance with what I have maintained, namely, that *neural processes* are uniform in character, the diversity of their results—sensation, motion, or secretion—depending on anatomical connections. *In itself*, a neural process is no more a sensation than it is a secretion. To determine a motor centre, therefore, we must look beyond the cortex, and detect its anatomical relations to the motor-apparatus. Do Dr. Ferrier's experiments prove that the area of the cortex, assigned by him as the motor area, has such anatomical relations to the motor apparatus, and the sensorial area such relations to the sensory organs, that we can speak of their activities as motor and sensorial *functions?* In other words, are the cortical areas to be regarded as playing the part of central functions or only of peripheral incitations?

He has argued his view with such force of fact and suggestion that I have little doubt of his carrying most readers with him; and because I dissent from his view I must occupy all my remaining space by endeavouring to weaken the effect of his argumentation. He considers that the indications naturally suggested by the observed facts of electrical stimulation are proved by the observed effects of disease and extirpation. Stimulation of particular spots is followed by definite movements; destruction of those spots is followed by paralysis of those movements. The reader is led captive by what seems irresistible logic. The evidence seems decisive. How if the evidence should be illusory? That it is illusory may be shown, I think, under three heads:—

First Head.—The Italian physiologists Lussana and Lemoigne have specially called the attention of experimenters to the fact that very many recorded contradictions result from the not distinguishing between the first and second experimental periods, namely, the effects observable soon after the operation, and the effects which are observable when the disturbance has settled down, and the organism has recovered something like its normal state ("Fisiologia dei Centri Nervosi," 1871). The first period comprises what may be called the effects of Disturbance of Function; the second period the effects of Removal of Function. The distinction, so fruitfully introduced by Dr. Hughlings Jackson, of discharging lesions and destroying lesions falls under the same conception. I will only add that neither the effects of Disturbance nor the effects of Removal are to be taken as conclusive evidence that the function disturbed or removed is the function of the organ operated on; but that whenever a function persists, or reappears, after the destruction of an organ, this is absolutely conclusive against its being the function of *that* organ.

This premised, I must suggest that Dr. Ferrier's experiments cannot be considered as conclusive, because he was unable to keep the animals alive long enough to allow the effects of Disturbance to subside, so as to leave only the effects of Removal to be estimated. And this is the more to be emphasised because in some instances the animals did survive long enough to show some subsidence of the disturbance and *some reappearance of the lost functions.* Now the reappearance of a function after the destruction of an organ admits of but two interpretations—either the function was arrested as an effect of the disturbance, or its organ was destroyed, and *another* organ had vicariously taken its place. This second interpretation is much in vogue, and has received the name of the law of Substitution. The notion that a function can be driven from organ to organ, "like a sparrow driven from one branch to another," as Goltz picturesquely says, is surely raising Hypothesis to the *n*th power? Dr. Ferrier without adopting the first of the two interpretations, argues against the second with his usual force; replacing it by one which is physiologically more consistent, namely, that "there is no direct establishment of new centres in place of those which have been lost, but that those which remain may indirectly without assuming new functions make up for the loss, to some extent at least." In these cases "the path from impression to action is not as in the ordinary course of volition through the cortical motor centres to the corpus striatum, and thence downwards to the motor nuclei and motor nerves, but through the basal ganglia directly." This fails to meet the case when, for example, the function of vision on one side disappears after removal of its assigned cortical centre, and nevertheless reappears. We cannot get the ear to do the work of the eye; and if touch does indirectly make up for loss of sight, it is by a slow process of acquisition; whereas the animal recovers its lost *sight*, and that in the course of a few days.

But restricting the explanation to movements, is it not a relinquishment of the hypothesis of voluntary motor centres? Is it not an invocation of the hypothesis of peripheral incitation? Observe this, moreover: Dr. Ferrier restricts his explanation to the movements which have been automatically organised in the corpora striata. All actions not become automatic are impossible after removal of the cortical centres. "It may confidently be asserted," he says, "and perhaps it may one day be resolved by experiment, that any special tricks of movement which a dog may have learnt would be effectually paralysed by removal of the cortical centres." Well, since this was written, experiment *has* decided the point. By an ingenious method of washing away cerebral substance, Goltz has been able to greatly diminish the disastrous effects of operation, and thus preserved the animals for weeks, in the course of which he observed an *almost* complete restitution of the lost functions. One of the striking cases recorded by him (Pflüger's *Archiv*, xiii. 31) is that of a dog who had been taught to "give the paw" on command. When the surface of the left hemisphere had been washed away there was at first a complete destruction of the power to give the right paw; and the dog when urgently called upon to give it, looked wistful, and ended by stretching out the left paw. Had the dog died within six days after the operation this might have been cited as proof of the destruction of a voluntary centre; but the dog lived, and on the eighth day began to give the right paw when asked, and a month afterwards gave it as readily as before the operation.

Second Head.—Under this head we may consider the evidence adduced for the existence of definitely circumscribed areas, and definite spots within those areas. Dr. Ferrier's pages are very instructive on this point, but not, I think, competent to force his conclusion when they are confronted with Goltz's experiments, which show that the paralysis of sensation and motion cannot reasonably be assigned to the destruction of particular spots, because the paralysis is dependent solely on the *amount* of substance washed away, and not at all on the *localities*. Add to which the fact just insisted on, that the paralysis is temporary. Dr. Ferrier believes that his experiments prove the distinct localisation of motor centres. For example, he produces inflammation and suppuration in one place, and observes spasms followed by paralysis of motion in the whole of one side of the body. This is urged in proof of motion being affected without affection of sensation. On examination, however, it seems to me only to prove the effects of disturbance; and this the more decisively, because he admits than when instead of an *irritating suppuration* there is *extirpation* of the centre, the paralysis quickly disappears. "In these experiments," he adds, "the power of movement alone was destroyed, sensation remaining acute and unimpaired." This is very ambiguous. Sensation *elsewhere*—on the other side of the body—was unimpaired; but so was power of movement *there*. In the paralysed limbs there was no sensation.

Let us now turn to a sensational centre: and we will select that of Vision, because the experiments are here most striking. Destruction of the "angular gyrus" on one side causes blindness in the opposite eye. But this is temporary, and begins to subside the next day 165). One would imagine that in presence of such observations, the fact of blindness would be attributed to Disturbance, not Removal of Function; and the recovery of vision to the subsidence of the disturbance. Dr. Ferrier interprets the recovery as due to the compensatory action of the centre in the other hemisphere (p. 169). But this is to invoke the Law of Substitution (which he has successfully refuted), and leaves unexplained why the compensatory action did not manifest itself from the first. The experiments of Goltz seem to me conclusive as to the observed blindness being merely the effect of disturbance; not only does the vision gradually return, but is proved not to depend on the conpensatory action of the intact centre, because it reappears even in an animal deprived of the other eye. That is to say a dog, with only one eye, had almost the whole of one hemisphere washed away, so that on the one side it had no optical apparatus, on the other no visual cortical centre—yet it showed unmistakable evidence of being able to see. Observe the dilemma: either there is a complete decussation of the optic nerves, so that each hemisphere is the sole centre for one of the eyes; or the decussation is partial, so that each hemisphere is a centre for both eyes. In the first case destruction of the one hemisphere should produce absolute and permanent blindness in one eye—and this is disproved by experiment. In the second case destruction of one hemisphere should produce partial blindness in both eyes—and this also is disproved by experiment. Or, finally, the visual centres are *not* in the hemispheres, so that destruction of the hemispheres is not destruction of vision—and *this* is what experiment proved.

Third Head.—I must be very brief on this point—namely, that very various effects ensue on excitation of one and the same spot. If we regard the cortex as a peripheral surface of excitation there is nothing mysterious in the various effects produced by reflexes from it—as from the skin; but if we regard it as a collection of distinct sensory and motor centres, there is great difficulty in reconciling the results of observation. For example, the so-called voluntary centres for movements of the limbs and tail are found by Bochefontaine to be centres of salivary secretion. In his memoir in the *Archives de Physiologie* (1876, No. 2, p. 169), the last-named experimenter sums up the results of his observations thus—that the hypothesis of cortical voluntary centres would lead to the conclusion that the same spot was the centre for voluntary movements in a limb, and involuntary contractions of the bladder and spleen, as well as dilatation of the pupil.

My space is exhausted, and I have not been able to do more than criticise the main topic of Dr. Ferrier's book—and this not with the fulness which its importance demands. But if I have shown grounds for regarding the hypothesis of voluntary centres in the cortex as at any rate far from *proved*, and in doing so have had to adopt an antagonistic attitude throughout my review, I should not be just to him, nor to my own feelings of gratitude, if I did not, in concluding, express a high sense of the value of his work, full as it is of suggestions, and rich in facts, which no counter-facts can set aside. It will long remain a storehouse to which all students must go for material. It may be the starting-point of a new anatomy of the brain.

GEORGE HENRY LEWES

SHELF

British Manufacturing Industries.—Edited by G. Phillips Bevan, F.G.S. "Jewellery," by George Wallis; "Gold Working," by Rev. C. Boutell; "Watches and Clocks," by F. J. Britten; "Musical Instruments," by E. F. Rimbault, LL.D.; "Cutlery," by F. Callis. (London: Stanford, 1876.)

THIS little volume (which is intended for popular reading) is comprised of several short essays, by different writers, upon the separate subjects indicated. Each essay contains a fairly good account of the history and general trade position of its subjects, but so far as their mechanical construction and the manufacturing operations involved therein are concerned, all are more or less disappointing. No doubt this is in great measure to be attributed to the nearly entire absence of diagrams, the essay on watches and clocks alone being illustrated, and that but scantily. Naturally some subjects suffer more than others. In jewellery, gold working, and cutlery the forms produced are familiar, the tools employed are simple, and what is the method of shaping and fitting together the various portions can easily be imagined. But with musical instruments and watches and clocks the case is different; people, *à priori*, are unacquainted with the apparatus or mechanism made use of, and a free reference to diagrams or figures becomes indispensable. In the essays upon jewellery and gold working, especially in the latter, their aspects and bearings as branches and developments of art are particularly dwelt upon. Cutlery, of course, is treated as an industry, so are watches and clocks. We are afraid the last-mentioned essay is not very carefully written, the writer, amongst other things, actually forgetting to tell us that there is any connection between the length of a pendulum and the time of its swing. And what he can be thinking of to describe Huyghens as a "French clockmaker of eminence," who "about 1650 showed great skill and ingenuity in arranging pendulums to clocks, so as to describe a cycloid," we do not know. The essay upon musical instruments (considering its not being illustrated) is much more intelligible than it might have been.

The book is neatly bound and printed, but will require considerable alteration and extension before it becomes what from its title we expected to find it.

An Introduction to the Osteology of the Mammalia. By Prof. W. H. Flower, F.R.S. 2nd Edition. (London: . Co., 1876.)

PROF. FLOWER'S valuable "Osteology of the Mammalia" holds so high a position among scientific manuals that the appearance of a second edition requires but a passing notice from us. The author is himself so continually adding to our knowledge of the anatomy of the higher Vertebrata, at the same time keeping fully *au courant* with the investigations of both British and foreign zoologists, that there are several minor additions which he has had to make after an interval of six years, since the appearance of the volume originally. Amongst the most important of these, we notice the record of the conical form of the odontoid process of the axis vertebra in the Chevrotains (*Tragulina*), the introduction of a summary of Prof. Parker's study of the development of the skull of the pig, the account of the hyoid bones of the Ant-eater, of the large pectineal process in Phyllorhine Bats, and of the peculiarly anchylosed tarsus in the Muntjacs. In the first edition the typography and the printing of the woodcuts was too black throughout; in the new one this defect has been entirely removed, both the type and the figures being all that can be desired. There is a new outline diagram of special interest introduced to illustrate the mutual relations of the various elements of what may be termed the typical mammalian skull. This replaces a plan drawn out for a similar purpose in which the names of the bones were distributed over a page in such a way as to indicate their relative positions. In the new diagram the employment of outlines to the bones renders the exact situation much more distinct and enables the commencing student to carry away with him a much more precise idea of the exact neighbourhood of each part of each bone than was possible from the older plan. We welcome with much pleasure this new edition of the "Osteology of the Mammalia."

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*]

On the word "Force"

PROF. TAIT in his lecture on *Force* said that this word must be used in a certain definite sense and in this sense only. In order to claim Newton's authority for the one definite sense to which he would confine the word, he has to assume, not only that Newton translated *force* by *vis impressa*, but that he—an Englishman writing in Latin—used *vis insita*, *vis motrix*, &c., without any English equivalents. Until good evidence for these assumptions—improbable as they are on the face of them—is brought forward, Prof. Tait cannot claim the authority of Newton *in his favour.*

In the communication I made to NATURE (vol. xv. p. 8) I contended that the authority of Newton was *against* the restriction of the word to this one sense, on the assumption that the equivalent of Newton's word *vis* is *force*. To those who demur to this assumption I propose the questions: (1) Is it likely that Newton had in his mind no English equivalents for *vis insita*, *vis gravitatis*, *vis centrifuga*? (2) If force is not English for *vis*, what English word had Newton in his mind? Until some new light is thrown on these questions I maintain that Newton's authority is claimed for the restriction of *force* to the sense of *vis* i on, to say the least, insufficient grounds; and that the obvious interpretation of Newton's words is dead against it.

I have, I hope, in a previous communication done justice to Prof. Tait's zeal for definiteness and accuracy; and with him I feel what supreme virtues these are in a scientific man. But I contend that the wide sense of the word *force*—which I attribute to Newton—is not loose and inaccurate; it is simply general and comprehensive; each of the narrower uses, as in *vis impressa*, *vis insita*, is not more accurate but more special: these special senses are not inconsistent, though they are not identical; they are neither inconsistent with each other nor with the use of the word force in its widest sense. Some English mathematicians wish to have this valuable word all to themselves for a special technical sense; Newton claims no such monopoly, nor is it claimed by all foreign mathematicians, nor conceded by metaphysicians; nor is the claim to this monopoly likely to be conceded until a better title to it has been shown.

Cambridge, November 24 P. T. MAIN

Peripatus N. Zealandiæ

IN the November number of the *Annals and Magazine of Natural History* is a paper by Capt. Hutton on *Peripatus N. Zealandiæ*, in which the author comes to the astounding results that this species is hermaphrodite, and that its horny jaws are not foot jaws but homologous with those of annelids such as Eunice. If such were in reality the case much of my results concerning *Peripatus capensis* (*Phil. Trans. R. Soc.*, 1874, vol. clxiv. Part 2) would lose its value, and since I believe *Peripatus* to be a most important form, and a representative of the ancestral stock of all tracheates, in fact of the Protracheata of Prof. Haeckel, I hasten to write a few words in reply.

I obtained specimens of *Peripatus N. Zealandiæ* at Wellington from Mr. W. T. L. Travers, who has done so much for science in New Zealand, and who most kindly assisted me and my late colleague, R. von Willemöes-Suhm, in many ways, and who first pointed out *P. N. Zealandiæ* to Capt. Hutton also. I had further at least fifty specimens of *Peripatus* collected for me and brought to me alive. I examined these and made notes, but have been prevented by other work from them hitherto. *P. N. Zealandiæ* is not hermaphrodite. I examined several males, which differ in no essential points in their structure from those of *P. capensis*. Like those of *P. capensis*, they are less numerous than the females, and Capt. Hutton has been unlucky enough not to meet with any amongst the twenty specimens examined by him. The jaws of *P. N. Zealandiæ* are further, I believe, developed just as are those of *P. capensis*. At least I saw that the earliest stages corresponded, and recognised the first pair of members of the embryo in *P. N. Zealandiæ* in the stage in which they are not yet turned inwards to become foot jaws. I have prepared a more extended answer to Capt. Hutton's paper with an account of my own observations on *P. N. Zealandiæ* for the *Ann. and Mag. of Nat. Hist.*, but as this cannot probably be published immediately, I should be much obliged if you would insert this reply in NATURE.

The Age of the Rocks of Charnwood Forest

IT is no doubt to be regretted that Mr. Woodward, misled by insufficient authority, should have introduced, in his excellent work on the geology of England and Wales, still further confusion into the maltreated old rocks of Charnwood Forest, but I doubt whether their age is quite so certain as Prof. Hull seems to think. I fully agree with him that there is not a particle of evidence for their Laurentian age, and that their syenites and hornblendic granites cannot be correlated with the hornblendic gneiss of the Malverns, but I must demur to his grouping them with the Cambrian rocks of the Longmynds or of Llanberis. The authority of Prof. Sedgwick is great, but it must be remembered that the term Cambrian with him included far more than in the nomenclature of the Geological Survey, and I am not aware that he ever committed himself to the Charnwood rocks being equivalent to his *Lower* Cambrians. Except a slight lithological resemblance of some Charnwood rocks to those of Harlech and Llanberis, and a still slighter to Longmynd rocks, there is really nothing in favour of this special correlation. One point, however, there is which may give some clue to their age, which does not seem to have been much noticed hitherto, probably because the facts have been strangely overlooked in the Geological Survey description of the district. It is that beds of coarse volcanic agglomerate and ash abound among the Charnwood series. Further, the resemblance of the rocks as a whole (when not unusually metamorphosed) is very close to the "green slate and porphyry series" (or Borrowdale rocks) of the Lake District. Compared with the Welsh rocks, they are far more like those of Cader-Idris than of Llanberis. With these there is scarce any lithological resemblance, but if I mixed my Charnwood collection with those from the other two localities, especially the former, I should have great difficulty in separating many specimens. It seems then to me far more likely that this great volcanic activity in the Charnwood district should have corresponded in time with that in the Lake District or with some part of that in Wales, than that it should have happened in the age of the Harlech, Llanberis, and Longmynd groups, where we have no evidence of any volcanic disturbance. The argument may be summed up thus, as it seems to me:—The Charnwood rocks are old, so are both the competing groups; they are unfossiliferous, so are both; they are cleaved, so are both; they contain evidence of great volcanic action, so do the Borrowdale series, and not the Welsh Lower Cambrians. One point for the former. The general correspondence of their strike with that of the Borrowdale series under Ingleborough may also perhaps count for something.

T. G. BONNEY

St. John's College, Cambridge, November 25

THOUGH the discussion of the age of the rocks of Charnwood Forest is not likely in the present state of our knowledge to lead to any useful result, there are still a few points in Prof. Hull's letter on the subject which seem to call for remark. In the first place the late Prof. Jukes was by no means so strongly in favour of the Cambrian age of these rocks as Prof. Hull states. Prof. Jukes' words, in Potter's (not Porter's) "History of Charnwood Forest" are as follows:—"It is therefore uncertain whether they (the rocks of Charnwood) belong to the Devonian, Silurian, or Cambrian systems, the probability only being in favour of the latter." Secondly, the Cambrian of Sedgwick includes a great deal more than the Cambrian of the Geological Survey, and therefore there is not the perfect unanimity between these two authorities that Prof. Hull's remarks would lead us to believe. Thirdly, if lithological resemblance is to go for anything, it may be used directly against the Cambrian age of the rocks. On the western side of the forest we find sheets of crystalline rock and beds of highly altered conglomerates and breccias, which have a suggestive likeness to the lava flows and ash beds of the green slate and porphyry series of the Lake District. I don't say the resemblance proves anything, but it is worth quite as much as the similarity between the slates on the east side of the forest and the slates of Llanberis. Mr. Bonney has also called attention to the fact that the strike of the Charnwood Forest rocks is the same as that of the Volcanic Series in the Lake Country, when that group is last seen. Again, it is far from certain that the rocks of Charnwood Forest are all of the same age. I recollect seeing many years ago some sections (of which I am afraid I have kept no record) that seemed to show that some of the bosses of Dioritic rock near Markfield were older than the slates that surrounded them. If this be so, perhaps these crystalline hills may be the projecting points of a nucleus of similar rock that underlies the whole area, and which may be Laurentian in age. The rocks are not gneiss, but I know of no reason why the equivalents of the rocks of the Hebrides must be gneiss all the world over; they are, however, rich in hornblende, and so are the Hebridian rocks. With all these possibilities before us, I am afraid it will be hard to arrive at that enviable state of security which Prof. Hull seems to have been in when he penned his letter.

A. H. GREEN

I AM pleased to find in NATURE, vol. xv., p. 78, a letter from Prof. Hull, with reference to the age of our Charnwood Forest rocks. He writes against their assignment by Mr. H. B. Woodward, in his "Geology of England and Wales," to the Laurentian period (see p. 24).

But, in fact, as Prof. Hull himself points out, we also find on p. 30 a statement that part of the series may belong to the Cambrian epoch.

It would appear that as Mr. Woodward is not personally acquainted with the region, he has endeavoured to give the views of the various authors whom he knows to have written on the subject, and as these are conflicting, and based upon little personal work, it is no wonder that he has been led astray.

I do not think sufficient importance has been attached to the study of this isolated outcrop of old rocks. We can trace its continuation to the south and south-east for a considerable distance, and I would venture to suggest the possibility of a flexure or spur in this direction connecting with the old palæozoic ridge for which we have lately been fishing in the Wealden. In my "Geology of Leicestershire and Rutland," which will shortly be published, there will be found some fine photographs of the principal quarries and natural outcrops of the Charnwood rocks; and I have there given the reasons which induce me on the whole to refer the main mass of the rocks to neither Laurentian nor Cambrian, but to the *Silurian* period. The evidence is but scanty however, but a balance of probabilities at the best. As to Sedgwick's determination of the region, we must remember that much that he then called Cambrian has since been assigned to Lower Silurian.

WM. JEROME HARRISON

Town Museum, Leicester, November 24

Minimum Thermometers

SOME time ago a correspondence appeared in NATURE (vol. vi. pp. 122, 142, 221) on the subject of moisture deposited in minimum thermometers exposed on the grass. As I was at the time much annoyed with this myself I took up every hint I could get in the matter, though I must confess with indifferent success. I tried for a long time india-rubber packing, with sealing-wax, &c., of varying coats, as advised, but still moisture insinuated itself.

At last I bethought myself of a *cork* packing. I cut a piece of cork so as to fit tightly round the neck of the thermometer tube, then inserted the tube and packing into the glass case—the cork packing being about a quarter of an inch long. The exposed end of the cork I covered with two or three coats of asphalte, as used on microscopic slides. At first a slight bubbling was seen through the asphalte, but soon disappeared, and a fine uniform surface at last set in. The thermometer has now been in use for several months, and not the least trace of moisture has ever been seen within the cases, although moisture has been abundant, especially for the last three months. The process is simple enough, and I venture to send it to you, hoping that it may answer the purpose for others as it has now for some time answered mine. THOMAS FAWCETT

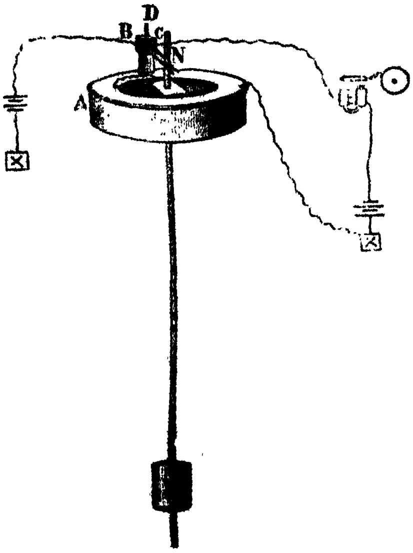
Blencowe School, Cumberland, November 6

Electric Motor Pendulum

THE following very simple apparatus may I think be of use in any laboratory or other place where at times it is necessary to have a pendulum beating seconds in order to give the time for any experiments needing it.

It consists of a Siemens' galvanoscope, A, to which is attached the pendulum; the needle N, preferably with platinum contacts, works between two platinum wires, B and C, with a small amount of play; these platinum wires are insulated from one another by being fastened into a piece of ebonite, which works on a pivot D. The needle is connected by its support to one end of the coil of the galvanoscope, the other end being to earth. To the wires, B and C, are connected the opposite poles of a small battery, the centre of the battery being to earth.

The action of the instrument is as follows:—On slightly oscillating the pendulum the needle N makes contact between B say, and the coil, the magnet being so arranged that the needle then deflects towards B, thus carrying with it the movable contact wires until the pendulum reaches its limit of oscillation, when it falls, breaks contact with B and makes contact with C, which thus tends to pull the needle over to C, and so on; in this way the pendulum receives at each oscillation the impulse necessary to overcome the forces tending to stop it; and thus will keep oscillating as long as the battery supplies the motive power. For small arcs the beat is *not affected by variation in battery power*.



In the circuit of the battery we can introduce an electro-magnet which at each contact of the pendulum on one side will make a stroke on a bell, or indeed by a detent will move by a small train of wheels the hands of a clock. If the pendulum is made to beat half seconds, then the contact being made alternately on each side, the bell stroke would beat seconds. We could of course introduce any number of arrangements of this sort at any intervals along the circuit, and so move any number of clocks at different positions in a large establishment, only one pendulum being requisite to control the whole set.

P. HIGGS

PROF. YOUNG ON THE SOLAR SPECTRUM

THE paper of Prof. C. A. Young read at the last meeting of the American Association for the Advancement of Science describing his recent measures of the displacement of the D and other absorption lines at the receding and approaching limbs of the sun, has a double interest.

By careful measures to which all the necessary corrections have been rigorously applied, obtained by using a diffraction grating in combination with a prism, Prof. Young deduces from observation of the D lines a value of 1·42 ± 0·035 miles per second for the surface velocity of rotation at the sun's equator Direct observation of the motion of spots gives 1·25 miles per second, and the author thinks that the difference of these two values being so many times larger than the probable error of the spectroscopic method, the result of which agrees so well with Vogel's result, indicates that a portion of the displacement observed is produced by the difference in the angular velocity of rotation of the solar atmosphere which causes the absorption lines and the underlying luminous surface, and the sign of the difference would indicate that the atmosphere is swept forward with the greater velocity of the two.

This conclusion is itself one of great interest, but for many persons the fact that it is based on the acceptance of Doppler's theory will be a source of satisfaction as indicating that the recent disputes as to its soundness are beginning to be considered settled and in its favour, as at any rate a near approximation to the truth.

One of its first assailants, on mathematical grounds, was Prof. Petzvall. But, as was pointed out by Mach in a "Contribution to Doppler's Theory," published at Prague, in 1874, his main argument fell beside the mark, while the only one which touched it went to prove that for comparatively small velocities of translation in the source of sound or light, compared to the velocity of wave transmission, Doppler's theory was a correct approximation.

More recently Van der Willigen's mathematical objections have been apparently fairly disposed of by Mr. Christie, while the discrepancy that Father Secchi has lately pointed out between the measures of displacement of spectral lines in the case of certain stars as observed by Mr. Huggins on the one hand and at Greenwich on the other, does not really affect Doppler's theory at all, but only the degree of certainty with which it can be applied to the determination of stellar motion. But the facts are not as Father Secchi represents them. He points out, in a list of thirteen stars, that the displacement in the case of some five stars as observed by Huggins is in the opposite direction to that observed at Greenwich. But the Greenwich observations that he takes are some early tentative observations. We have taken the trouble to refer to the most recent Greenwich measures, and find that of the five disagreements insisted on only one holds.

INDIAN GEOLOGY

THERE seems to be a very pretty quarrel just now—and one urged with the usual absence of acrimony in scientific controversies—as to the age or ages of an important group of rocks in Her Majesty's Indian empire.

For years it has been known that while a large mass of the rocks forming the Peninsula of India are unfossiliferous, there is also in that country an extensive series of beds the predominant, and frequently the only, fossils of which are vegetable remains. These beds were often spoken of as the Plant-beds of India. Among the flora certain forms which used to be called *Palæosamiæ*, now *Ptilophyllum*, were pretty generally distributed, while the genera *Schizoneura* and *Glossopteris* were found in lower portions of the series.

On the evidence of the first-named fossils and several others, a Jurassic age was assigned to the containing beds, while the identity of the *Glossopteris* with Australian forms involved these Indian beds in the dispute as to whether the coal-rocks of that country were likewise Jurassic or really carboniferous.

One portion of the Indian plant beds contained a limited terrestrial fauna which on high authority (Huxley) was considered probably Triassic. And another portion of this plant series (in Kutch) was found associated with a marine fauna ranging from the age of the Bath Oolite up to the Tithonian of Continental geologists.

On the whole question, the Triassic fossils, though their suggestiveness was admitted, were not considered sufficient to have much influence, and to the upper part of the plant-beds a Jurassic age was assigned, while the lower portion, apparently on the evidence of the *Glossopteris*, was thought to be Palæozoic, an opinion, however, which does not appear to have been universally received.

In this state, or one very similar, Dr. Feistmantel found the subject upon commencing his examination of the Indian fossil plants, aided by the separation of the series into several groups on stratigraphical grounds by the officers of the Geological Survey.

His examination has led to results so far as yet published, which will be found in two papers among the *Records* of the Geological Survey (vol. ix., parts 2, 3).

From these it appears he considers the Kutch flora to represent a period in the Jurassic epoch somewhat earlier than that indicated by the associated marine fauna, so far as this has been examined, which is one of the points in debate, and that five of the upper divisions of the Indian plant beds (or Gondwana series) are Jurassic, while he contends that the remaining three of its lower groups are neither Jurassic nor Carboniferous, but Triassic.

In a paper immediately following Dr. Feistmantel's second contribution to the *Records* of the Indian Survey, Mr. W. T. Blanford discusses the whole question, and arrives at the conclusion that the evidence connecting the lower Indian plant beds with the Australian carboniferous rocks is about equal to that for their being of the same age as the Trias of Europe—pointing out that the land faunas and floras of Palæozoic and Mesozoic times differed from each other in different parts of the globe, at least as much as they do at present, and far more than the fauna of the sea. Also that the evidence founded upon fossil plants of the age of rocks in distant regions must be received with great caution, being certainly in same cases opposed to that furnished by the [contemporaneous] marine fauna.

In a coming volume of the "Palæontologia Indica," Dr. Feistmantel will no doubt state his views and their reasons as fully as possible; meantime, enough has been said to show the interesting, yet rather difficult, nature of the subject, for more detail regarding which the papers just mentioned may be referred to.

THE RIVER CLYDE

THE profession of Civil Engineering, as defined by Telford, which definition is incorporated into the Charter of the Institution of Civil Engineers, is "the art of directing the great sources of power in Nature for the use and convenience of man," and there are few more striking examples of what science may do for commerce, or of what man may accomplish by working hand-in-hand with Nature than is the proud position of the River Clyde at the present day, as compared to what it was one hundred years ago, or even as late as the year 1840.

To many of those who attended the recent meeting of the British Association, and who have fresh in their memory the geography of the City of Glasgow, with which must indissolubly be connected the princely hospitality of its inhabitants, it may be interesting to know that the noble river which has made Glasgow the mighty city that it is, from whose shores some of the largest ironclads of our fleet have been launched is a water highway, almost as much the work of man as is the Suez Canal itself.

One hundred years ago the Clyde was little more than a picturesque mountain-stream, so shallow, that at a place called Dumbuck Ford, twelve miles below Glasgow Bridge, passengers could traverse it on foot. Now, vessels drawing twenty-three feet of water can ride safely in the heart of the city at low water, and the largest ocean-going steamers can come up the river at all times of the tide.

This wonderful change has been brought about by a succession of engineering operations, in all of which Nature has been coaxed, by artificial means, into doing the largest share of the work; and the operations of man, great as they have been, have been directed solely to assist that work, and to remove obstacles which stood in its way. The names of the engineers under whose directions these improvements have been made, alone show that the highest scientific skill has been brought to bear upon the development of the water-way to the City of Glasgow; for, within the last 100 years, among the engineers who have been employed by the Clyde trustees, either to carry out improvements, or to prepare reports in connection therewith, will be found the names of Smeaton, Golborne, Watt, Sir John Rennie, Telford, Stevenson, Walker, Scott Russell, and Bateman; but the largest engineering operations have been left for Mr. Deas, the present engineer of the Clyde navigation to carry out, for since the year 1872 greater progress has been made than during any previous equal period. In that time no less than 1,505 lineal yards of quayage have been added, slip and graving-docks have been constructed, large cranes erected, and very considerable progress towards completion has been made in the celebrated Stobcross Docks of which we shall speak further on.

The exceptional construction of these docks, necessitated by the local peculiarities of the geological strata, formed the subject of a valuable paper read before the British Association by Mr. James Deas, C.E., under whose directions they are being constructed, and who has recently published a most interesting work upon the Clyde,[1] illustrated with maps, sections, and tidal diagrams, and from which many of the data contained in this article have been derived, and to which we would refer those of our readers who wish for further investigation.

It is just a hundred and eight years ago since John Golborne, of Chester, visited the Clyde and made his first report, in which he pointed out that the shores of the river "in most places being much softer than the bottom, the current has operated there, because it could not penetrate the bed of the river, and has by those means gained in breadth what is wanting in depth;" and, he added, "I shall proceed on these principles of assisting Nature when she cannot do her own work, by removing the stones and hard gravel from the bottom of the river where it is shallow, and by contracting the channel where it is worn too wide."

Golborne, carrying these principles into practice, erected a number of rubble jetties so as to contract the channel, giving to the stream greater rapidity, and consequently greater scouring power, and by a system of dredging in the deeper shallows, and horse-ploughing in those which were exposed at low water, he loosened the hard crust forming the bed of the river, exposing to the action of the current the softer material below, which was speedily scoured away, and in less than eight years the depth of water at Dumbuck Ford was increased from 2 feet to 14 feet. Golborne was followed by Rennie, who, in 1799, recommended the shortening of some of the jetties, the lengthening of others, and the construction of new ones, so as to direct the channel in its proper course with the least obstruction to the water; and to insure this he recommended building rubble walls from point to point of the jetties, so as to avoid the formation of shoals between them. These suggestions were carried out by the Clyde mistakes in transmission can be traced to the station and person where they occur.

---

[1] "The River Clyde; an Historical Description of the Rise and Progress of the Harbour of Glasgow." By James Deas, M.Inst.C.E. (Glasgow: James Maclehose, 1876.)

The Recorder consists of a powerful electro-magnet, between the poles of which a coil of fine insulated wire is delicately suspended, so as to be able to move round a vertical axis. The current from the cable is made to pass through this coil of wire. When a current passes through a coil suspended between the poles of a magnet, the coil tends to take up a position with its plane at right angles to the line joining the poles. There are two weights suspended from the bottom of the coil, which, when no current is passing, keep the plane of the coil in the line joining the poles of the magnet. When a positive current is passing, the coil tends to turn round a vertical axis in one direction, and when a negative current is passing, it tends to turn round in the opposite direction.

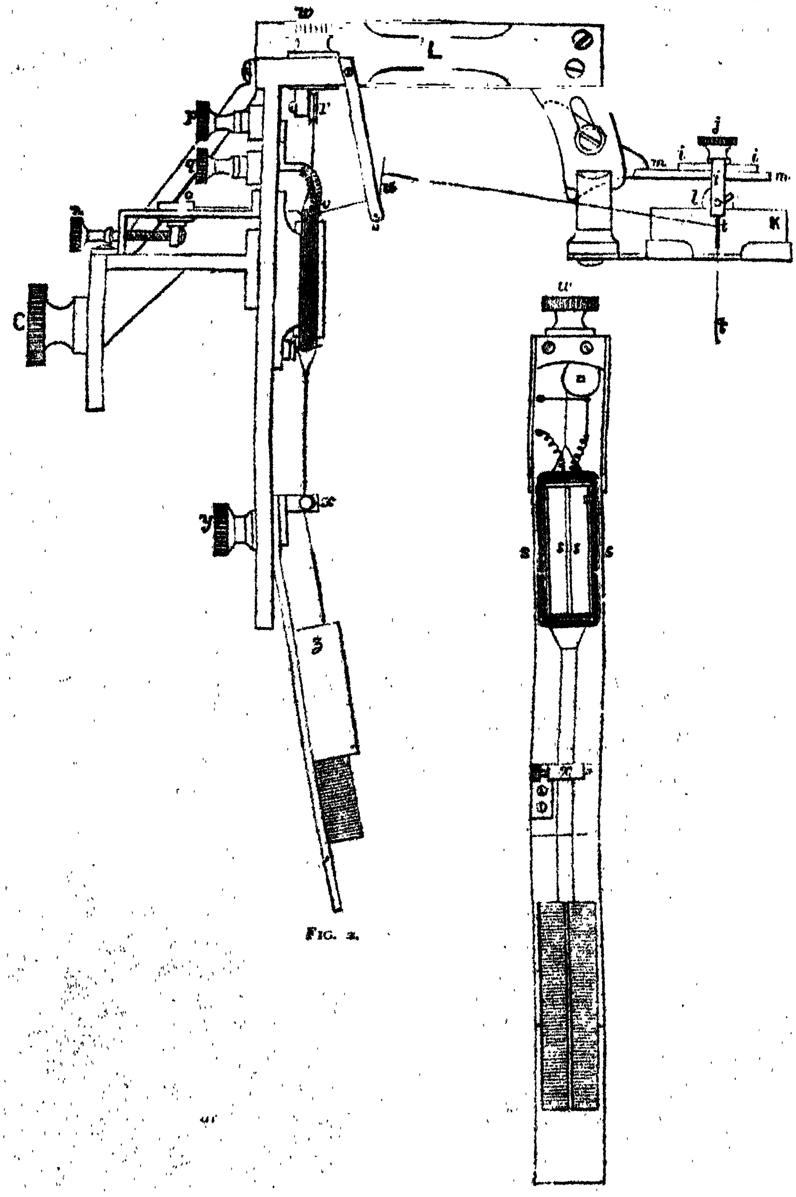


FIG. 2.

FIG. 3.

The coil is connected by means of silk fibres with a very fine glass siphon, suspended so that one end dips into a metal box containing ink, and the other end hangs down nearly touching a paper ribbon. The motion of the coil is thus transmitted to the glass siphon. The metal box containing the ink is insulated and is electrified by means of an electrostatic induction machine while the paper is connected with the earth. The ink being electrified, is drawn from the point of the siphon and spurted out in small drops on the paper. When no current is passing they form a straight line on the paper as it is drawn past the end of the siphon; but when a current passes through the coil, it being deflected, draws the siphon to one side, and the line on the paper is no longer straight, but indicates the deflections of the coil. The well-known Morse alphabet is used with the recorder. A deflection of the siphon-point to one side corresponds to a dot, and one to the opposite side to a dash.

Fig. 1 shows a front view of the Recorder. B is the electrostatic induction machine, called the mouse-mill, which is driven by an electro-magnet inside the box D. The mouse-mill serves two purposes. It generates electricity, which is communicated to the box K, containing the ink, by means of the rod P, and it draws the paper along, past the siphon point. M M are the electro-magnets and S is the coil of wire suspended between them; *t* is the siphon, one end of which dips into the ink-box K, and the other end is almost touching the paper *c*. The paper passes under the spring *a* which keeps it stretched, over the roller *b*, then vertically down, past the siphon point, to the driving drum *d*. The battery used for the electro-magnet M M and for the mouse-mill is of the form of Daniell's battery known as the *Tray* battery. It is fully described in NATURE, vol. vi. p. 32.

Fig. 2 is an enlarged view of the signal coil and siphon. Fig. 3 shows a front view of the suspension of the coil. S is the coil suspended by a silk fibre passing round the pulley *r*. From the coil hang two weights, which can slide up and down the guides *s*. The coil surrounds a stationary piece of soft iron placed there for the purpose of increasing the intensity of the magnetic field. A silk fibre *v* connects one corner of the coil with one end of a vertical lever U. The other end of the lever is connected to the siphon *t* by means of another silk fibre, and the motion of the coil is thus communicated to the siphon.

In consequence of the electrostatic capacity of submarine cables, a retardation occurs in the transmission of signals, so that when a current enters at one end of a cable, a certain time elapses before any effect can be detected by the most delicate instrument at the other end. Fig. 4, Curve I., represents the strength of the current, received at the remote end of a cable, as it gradually increases, when the end operated upon is connected to one pole of a battery and kept permanently so. The vertical ordinates represent the strength of the current. The horizontal ordinates represent intervals of time reckoned from the first application of the battery in terms of an arbitrary unit, *a*. This unit of time, *a*, may be defined as follows:—Suppose a cable electrified so that the electrification along the cable may be represented by a harmonic curve, with single maximum in the middle and zero at each end. Now let both ends be connected to earth. Then the time that the harmonic electrification takes to subside to three-fourths of its initial value is denoted by *a*. Curve I. coincides so nearly with the line, O X, at first, as to indicate that there is no sensible current until the interval of time corresponding to *a* has elapsed; although, strictly speaking, the commencement of effect at the remote end is instantaneous. After the interval, *a*, the current rapidly increases in strength. When an interval of time equal to 5*a* has elapsed from the first application of the battery, the current will be about half its ultimate strength. After 10*a*, the current will have attained to nearly its full strength, that the further increase will be scarcely sensible. Theoretically the full strength is not reached until an infinite time has elapsed.

Fig. 4, Curve II., shows the effect at the remote end of applying a battery during a time equal to 4*a*, and then putting the cable to earth. It will be observed that a current gradually diminishing in strength continues to flow out of the cable for a considerable time after the battery has been disconnected. It is this after-effect which interferes so seriously with the working of submarine cables.

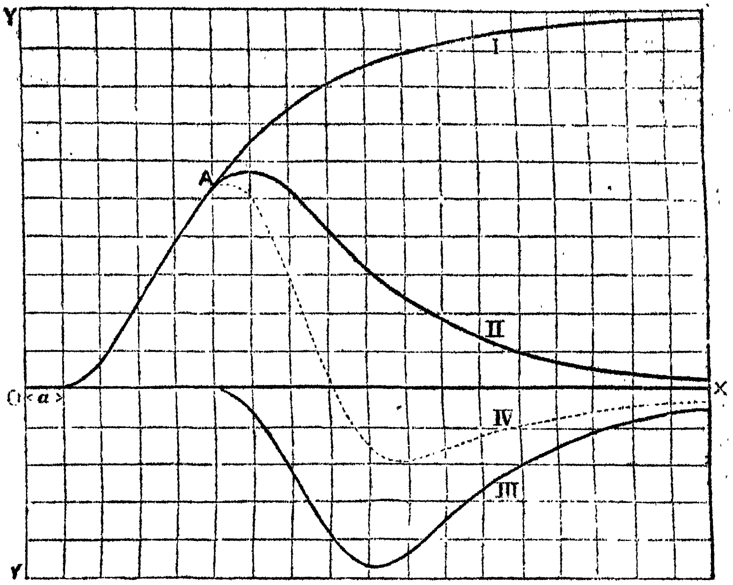

FIG. 4.

The Automatic Curb Sender was designed by Sir William Thomson and Prof. Fleeming Jenkin for the purpose of diminishing the effects of the retardation due to the electrostatic capacity of submarine cables. This was accomplished by making each signal consist of two currents, the second being of opposite name to the first and of a shorter duration. The latter, or curbing current, hastens the neutralisation of the cable after the first current has passed, and tends to do away with the effects of the first current. For example, let one end of the cable be connected to one pole of a battery for an interval of time equal to 4*a*, and then let it be connected to the opposite pole for a time 3*a*. The effect at the remote end of this latter current, if it had occurred alone, would be represented by Curve III. of Fig. 4. The joint effect of the two currents is represented by Curve IV., whose ordinates are the algebraic sum of the ordinates of Curves II. and III. The quick return of Curve IV. to the zero line OX, as compared with Curve II., shows the advantage of curb sending.

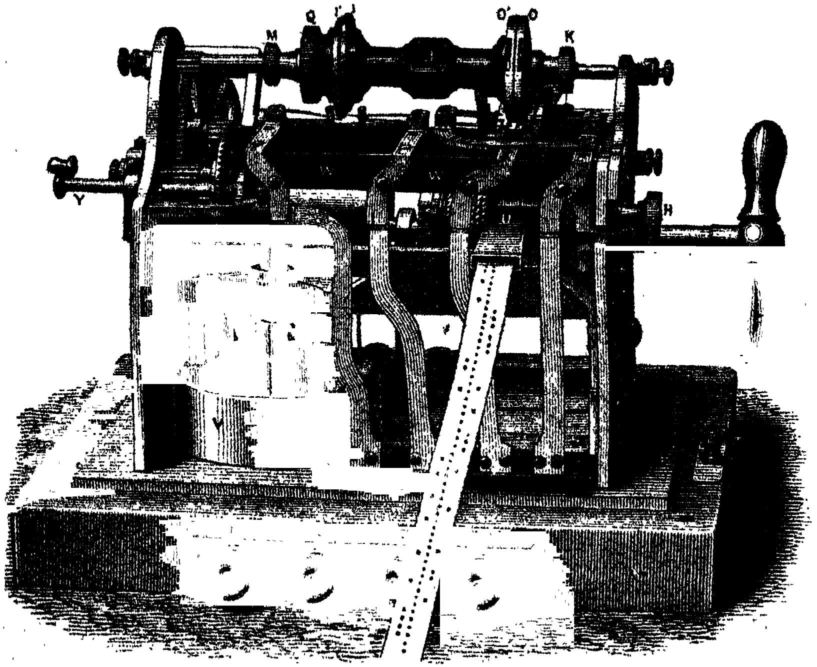

FIG. 5.

The curve traced out by the point of the siphon represents the curve of arrival, and the effect of curb sending is to give a sharp outline to the signals and to bring the point of the siphon back or nearly back to the zero line between each signal. It is necessary for the success of curb sending that the spaces for the signal and curb currents should be perfectly correct, and this can only be effected by means of automatic mechanism.

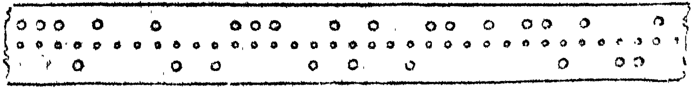

FIG. 6.

Fig. 5 is an engraving from a photograph of the automatic sender. The message to be sent is punched on a strip of paper in right and left holes, which correspond to the dot and dash of the Morse alphabet, and a central row of holes is punched for the purpose of carrying the paper through the machine. The paper is then put into the machine and drawn along at a uniform speed by means of clock-work. The paper passes through the tube U and underneath two prickers placed so as to correspond to the right and left holes in the paper. When a right or left hole passes, the corresponding pricker falls into the hole, and in doing so lifts a spring through the opening *l* or *l′* into the rim of the revolving wheel O O′. The spring being caught in the rim of the wheel is obliged to remain there until the wheel makes one complete revolution, and the opening in the rim returns to free it. The wheel makes one revolution while one space passes the pricker. When the spring is lifted into the rim of the wheel it makes connection between the battery and another set of springs. The latter set of springs are acted on by a double cam, I I′, which is connected with the same shaft as O O′, and revolves with it. During one revolution this double cam by means of the second set of springs sends first one current from the battery into the cable, and immediately afterwards a second current of the opposite name and of rather shorter duration. The first current is the signal and the second is the curb current. If a left-hand hole in the punched paper passes, and the corresponding pricker falls into it, a positive current will be sent first, followed by a negative current, but if a right-hand hole passes, the first current will be negative, followed by a positive one.

Fig. 6 shows the appearance of the punched paper when it is prepared for the Automatic Sender. The specimen represents the signal "understand" and the first seven letters of the alphabet.

ON THE CONDITIONS OF THE ANTARCTIC[1]

MY principal object in this evening's lecture is to direct your attention to some of the peculiarities in the physical conditions of the Antarctic regions, and to put you in a better position to contrast these with the more generally known phenomena of the Arctic; and it seems specially appropriate to allow our thoughts to travel for an hour towards that other fortress of the Ice King, a fortress apparently even more hopelessly impregnable, now while the pulse of the nation is still throbbing in sympathy with the brave little band who have just added another chapter to a long and terrible record of daring and self-sacrifice, and have succeeded in the face of almost unparalleled hardships in once more planting the Union-Jack nearest to the North Pole. The propriety is all the greater seeing that Capt. Nares, the gallant leader of the northern explorers, is also the last of the few navigators who have crossed the Antarctic Circle.

I will first of all then give you a brief sketch of our Antarctic experiences in the *Challenger*, and then go on to consider what may be the most probable explanation of some of the most striking of the appearances which we observed.

After spending about a month at Kerguelen Island, making meteorological and other observations, and selecting a suitable spot for the observation of the transit of Venus by the English astronomical party in the following season, the *Challenger* left Christmas Harbour on January 31, 1874, and on February 6 we reached the desolate little group of the Heard Islands, and on the 7th continued our course southwards.

Early on the morning of the 11th a large iceberg was observed bearing south-south-east about six miles off. The berg was table-shaped, the top perfectly flat and covered with a dazzling layer of snow. The perpendicular ice-cliffs bounding it were of a delicate pale blue, apparently perfectly clear, with some caves and slight recesses, where the blue was of a deeper shade. The height of the berg above the sea was 219 feet, and its extreme length by angular measurement was 2,202 feet; so that, supposing it to be symmetrical in shape, the contour of the visible portion being continued downwards, its depth below the water may probably have been about 1,500 to 1,800 feet. In the afternoon Lord George Campbell observed during his watch a large piece come off the side, dashing up the spray, and we afterwards saw a quantity of fragments floating off.

The 12th was misty, with a breeze force = 3-4 from the north-west by west. Many icebergs came in sight from time to time and quickly became obscured in the mist. The position of the ship at noon was lat. 62° 36′ S., long. 80° 4′ E.

Towards evening we passed close to a very beautiful iceberg. One part of it was rounded and irregular in form, putting us in mind of the outline of the Sphinx, and another portion, separated from the first by a fissure, the sea dashing through between them, was like a fragment of a colossal cornice. As the sun sank the ice took a most lovely pink or mauve tint, and when we came close up to the berg it showed out veined in a wonderful way with lines of deep cobalt blue. The ice was perfectly pure and clear. The bergs which we were passing at this time seemed to be breaking up very rapidly; some large fragments had been detached from this one shortly before we reached it, for a quantity of *débris* was floating at a little distance. The pieces washing about in the water very soon lose their edges and angles, and get rounded, and shortly disappear.

The 13th was a fine day, with a light wind from the north-north-east and occasional snow showers. There were some large tabular icebergs along the southern horizon. In the afternoon we passed close to a beautiful berg, very irregular in form, all the curves and shadows of a most splendid blue. The lower portion of the side of the iceberg next us formed a long steep slope into the water, and up this slope the surf ran with every heave of the swell, taking in its course the glorious blue of the ice and ending at the top of the glacis in a line of glittering foam.

The evening fell grey and slightly misty, with a number of icebergs looming through the mist. One or two of us were standing on the bridge about midnight looking at what seemed to be a low bank of white fog coming down upon us, when all at once a universal grating and rasping sound and sensation seemed to pervade the ship, and looking over the side we found that instead of sailing in open water we had passed into the edge of the pack, and as far as the eye could reach to the eastward the sea was closely covered with blocks of ice of all sizes up to six or seven feet in length among which the ship ground her way. A cold-looking moon struggled faintly through the cloud and mist and showed the pack vaguely for a mile or so ahead, covered with a light fog through which we could just see several icebergs looming right ahead of us and on either bow, and the masses of ice becoming larger and forming a closer pack as we passed inwards from the outer edge.

It was a wonderful and in a certain sense a beautiful sight, but one which would certainly require for its full enjoyment very fine weather such as we had, or a specially strengthened ship.

The necessary orders were given, and we veered round and slowly passed out of the pack and into open water; and we hung about beyond the line of wash-ice for the short Antarctic night.

On the following morning there were icebergs all round us, some of them of very fine forms. One which we saw all day on the port quarter was gable-shaped with a glorious blue Gothic arch in the centre, and a separate spire over 200 feet high. It was like a gorgeous floating cathedral built of sapphire set in frosted silver.

All day the pack could be seen from the deck stretching away to the east and south as far as the eye could reach, a mass of rugged glittering blocks one piled on the top of another. The ice-blink, a beautiful and characteristic phenomenon, was very marked above the pack—a clear band of white reflection rising some 12° above the horizon, and frequently bounded above by a dark-rolled cloud.

---

[1] The substance of a lecture by Sir C. Wyville Thomson, F.R.S., delivered in the City Hall, Glasgow, on November 23, under the arrangements of the Glasgow Science Lectures Association.

The 15th was clear and calm, with a light wind from the south-east. There were innumerable icebergs in all directions, some with their blue cliffs entirely visible from the bridge, and the blue waves lapping about their base, and springing up into fissures and recesses in jets of dazzling foam; some only rising above the horizon and slowly developing their varied outlines, and for a time deluding us into the idea that they were low—sloping gently from the water, and that it might be possible to land upon them. All the very large bergs, and some of them were one or two miles in length, were table-topped, evidently retaining their original position.

About 10 o'clock in the evening our attention was called by the officer of the watch to a very beautiful effect of light. There had been a fine crimson sunset, and now a dark curtain of cloud had sunk almost to the water's edge, leaving between it and the sea a long open line of the most vivid flame-colour, broken here and there by an iceberg, which, according to its position, took a rosy glow from the sky, or merely interrupted it with its cold grey outline.

During the forenoon of February 16 we passed on under sail through a splendid double chain of icebergs, most of them table-topped, and showing little evidence of change of form; and all day, on the southern horizon, berg after berg rose solemnly out of the water, at first a white line only, the blue bounding-cliff growing in height as we ran southwards. Shortly after noon we crossed the Antarctic circle, and a little later we reached our most southern point, lat. 66° 40′ S.; long. 78° 22′ E. exactly fourteen hundred miles from the South Pole.

As the season was advancing, and as there was no special object in our going further south—a proceeding which would have been attended with great risk to an unprotected ship, since, while the temperature of the surface-water ranged between – 1°·67 and – 2°·0 C. (29° and 28°·4 F.), very close to the freezing-point of sea-water, the temperature of the air fell to – 4°·44 C. (24 F.), and once or twice the water began to show that sludgy appearance which we know sets so rapidly, converting in a few hours an open pack into a doubtfully penetrable barrier—Capt. Nares decided upon following the edge of the pack to the north-eastward, towards the position of Wilkes' "Termination Land."

From our most southern point the sea was tolerably clear of ice for at least twenty miles in a south-westerly direction. The whole of the horizon to the south-east was closed by a chain of very uniform and symmetrical flat-topped bergs, all about 200 feet high above the water, one upwards of three miles in length, and several between one and two miles.

During the next week we were making our way slowly to the north-east, along the edge of the pack, sometimes dipping into it a little way, or crossing outlying loose patches.

The pieces of ice on which we were bumping every now and then were 10 to 20 feet in length, rising from 1 to 2 feet out of the water. Most of them were covered with a smooth layer of lately fallen snow, which had apparently not even got splashed with the water which was lapping round the blocks, it was so pure and white.

When the ship struck a block, the ice was usually driven aside unbroken; but the crust of snow was shattered and fell into the water. At the line where the water broke against the ice-blocks, they were all more or less honeycombed and worn-looking, and along this line many of them were of a dirty-yellow colour, probably from the washing of diatoms and crustaceans into the spongy ice. The temperature of the air averaged about – 4°·7 C. (23°·5 F.) in the shade; and that of the surface of the sea – 2°·78 (27° F.); every overhanging ledge of an iceberg was fringed with delicate new icicles, and the "gummy" look of the surface, threatening the formation of young ice, was very evident. The sea was usually a splendid deep blue.

The weather changed during the night of the 23rd, and at daylight on the morning of the 24th the wind was rising fast with a cloudy sky and frequent snow-showers. We were very anxious to get a haul of the dredge in this position, and Capt. Nares had it put over in the hope of getting it up before the weather became too boisterous. The wind and sea rose so fast, however, that it was found necessary to shorten the operation. The dredge was got in safely, but, as we anticipated, it was empty, and had probably never reached the bottom. During the forenoon the weather got rapidly worse. The snow became continuous, and was so thick—blinding clouds of singularly beautiful wheel-like crystals, which stung the face as if they were red hot—that we could scarcely see the length of the ship. We tried to get under the lee of an iceberg; but while reefing an eddy caught the ship and dragged her towards the berg, which she fouled, carrying away her jibboom. At three P.M. things were nearly as bad as they could be. The wind was blowing from the south-east by east, with a hurricane force, in the squalls; the sea was running very high; the temperature had fallen to – 6°·11 C. (21° F.); we were surrounded with icebergs, which we could not see for the sheets of blinding snow, but we could hear the dull boom of the surf dashing upon them. When the gale was at its height we saw the loom of an iceberg on the lee-bow, and we were drifting directly upon it. As there was no time to steam ahead, Capt. Nares went full-speed astern with the four boilers, and set the reefed main topsail aback, and under this sail the ship fortunately gathered stern-way, keeping broadside to the wind, and we drifted past the berg. Towards evening the wind fell a little, and we moved about all night between two bergs, whose position we knew, keeping as much as possible under their lee till daylight.

On the morning of the 25th this storm, which was one of the most trying and critical episodes in the whole voyage, was entirely over, and the air was calm and clear. We pushed a couple of miles into the pack to the north-east. We were now about fifteen miles from the position of Termination Land on the chart sent by Lieut. Wilkes to Capt. Ross. The sky was clear to the southward and eastward, the direction of the supposed land, but there was nothing which could be taken even for an "appearance of land." A sounding taken close to the edge of the pack had given a depth of 1,300 fathoms, and there was no trace of land *débris* on any of the icebergs. We were forced to conclude that Lieut. Wilkes had been in error, and that there was no land in this position. We now ran on steadily in a north-easterly direction towards Cape Otway, and on March 4 we passed a low irregular iceberg, the last we saw during our southern cruise of 1874. We sighted Cape Otway on March 16, and on the 17th we anchored off Sandridge Pier, in Hobson's Bay.

In these high southern latitudes, at all events at the point where we crossed the Antarctic circle, it seems that originally all the icebergs are tabular, the surface perfectly level and parallel with the surface of the sea, a cliff on an average 200 feet high bounding the berg. The top is covered with a layer of the whitest snow; now and then a small flock of petrels take up their quarters upon it, and trample and soil some few square yards, but after their departure one of the frequent snow showers restores it in a few minutes to its virgin whiteness. The upper part of the cliff is of a pale blue, which gradually deepens towards the base. When looked at closely, the face of the cliff is seen to be traversed by a delicate ruling of faint blue lines, the lines more distant above, and becoming gradually closer. The distance between the well-marked lines near the top of the berg may be a foot, or even more; while near the surface of the water it is not more than 2 or 3 inches, and the spaces between the blue lines have lost their dead whiteness and have become hyaline or bluish. The blue lines are very unequal in their strength and in their depth of colouring; sometimes a group of very dark lines gives a marked character to a part of a berg. Between the stronger blue lines near the top of the cliff a system of closer bands may be observed, marking the division of the ice by still finer planes of lamination, but these are blended and lost in the narrower spaces towards the water-line. The blue lines are the sections of sheets of clear ice; the white intervening bands are the sections of layers of ice where the particles are not in such close contact—ice probably containing some air.

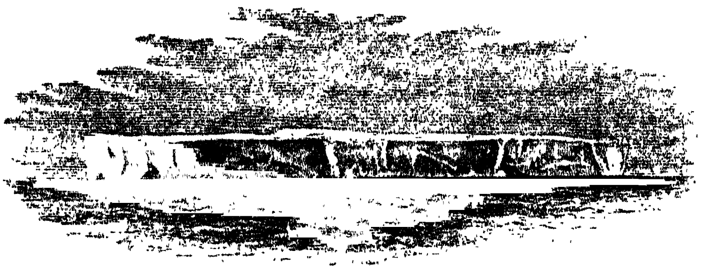

FIG. 1.—February 11, 1874. Lat. 60° 52′ S., Long. 80° 20′ E.

The stratification in all the icebergs which we saw, was, I believe, originally horizontal and conformable, or very nearly so. In very many of them the strata had become inclined at various angles, or vertical, or reversed; in many they were traversed by faults, or twisted or contorted or displaced, but I never saw a single instance of deviation from the horizontal and symmetrical stratification which could in any way be referred to original structure; which could not, in fact, be at once accounted for by changes which we had an opportunity of observing taking place in the icebergs.

I think there can be no reasonable doubt from their shape, and from their remarkable uniformity of character, that these great table-topped icebergs which we saw all around us, and closing in our southern and eastern horizon at the southernmost point of our voyage, and breaking down and melting a little further to the north, are prismatic blocks riven from the edge of the great Antarctic ice-sheet, portions of whose vertical cliff were seen by Ross in January, 1841, and in February, 1842, in lat. 78° 4′ and lat. 77° 49′ S. to the southward of New Zealand, and by Lieut.-Commandant Ringgold in the U.S. ship lat. 65° 49′ S. There is unfortunately great difficulty in determining when the wall of ice to which the term "ice-barrier" was restricted by Capt. Ross was seen by Lieut. Wilkes or any of his party, since Lieut. Wilkes applies the term indiscriminately to the solid ice-walls and to the masses of moving pack by which his progress was from time to time interrupted. The wall is satisfactorily described at one or two points only.

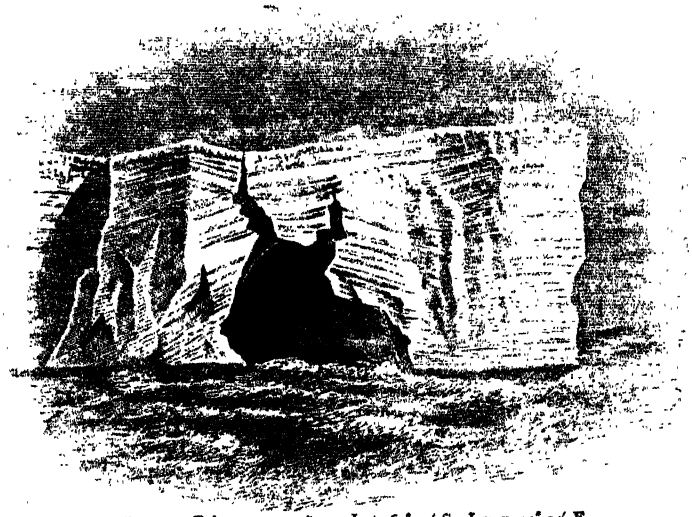

FIG. 2.—February 23, 1874. Lat. 64° 15′ S., Long. 93° 24′ E.

I believe that the stratification of those portions of the icebergs which were visible to us is due entirely to successive accumulations of snow upon a nearly level surface. The spaces between the transverse blue lines on the bergs may possibly represent approximately the snow accumulation of successive seasons. The direct radiant heat of the sun is very great in these latitudes, and during summer the immediate surface of the snow is frequently melted in the middle of the day, the water percolating down among the snow beneath and freezing again at night, or when it has trickled down into the shade. This process repeated every clear day for the two or three months of summer might well convert a very considerable belt of snow into ice more or less compact. That the process does go on we had ample evidence in the icicles fringing the snow which was lying upon flat pieces of the pack, which dropped rapidly in the sun even when the thermometer in the shade was several degrees below the freezing point.

The finer laminations may probably indicate the more feeble results of the same process after successive snowfalls. As I have already said there was not, so far as we could see, in any iceberg the slightest trace of structure stamped upon the ice in passing down a valley, or during its progress over *roches moutonnées* or any other form of uneven land; the only structure except the parallel stratification which we ever observed which could be regarded as bearing upon the mode of original formation of the ice-mass was an occasional local thinning out of some of the layers and thickening of others, just such an appearance as might be expected to result from the occasional drifting of large beds of snow before they have time to become consolidated.

We certainly never saw any trace of gravel or stones or any foreign matter necessarily derived from land on an iceberg; several showed vertical or irregular fissures filled with discoloured ice or snow, but when looked at closely the discoloration proved usually to be very slight, and the effect at a distance was chiefly due to the foreign material filling the fissure reflecting light less perfectly than the general surface of the berg. In one or two distant bergs there seemed to be thick horizontal beds of ice deeply coloured brown or bottle-green, but this was also, I believe, chiefly an effect of light.

In the pack, which is made up of fragments of all sizes of berg-ice mixed with masses of salt-water ice, the berg-ice is almost always either white with pale-blue streaks, blue with a white opalescence, or rarely deep blue, or still more rarely black from absolute transparency; it is seldom soiled in any way. It is so occasionally; on the 10th we passed, not far from our turning-point, a piece of berg-ice with a small flock of penguins upon it. The birds had evidently been there for some time for the snow on the surface of the ice was trampled into a dirty brownish mud; another fall of snow would have converted this layer into a discoloured vein in the block.

C. WYVILLE THOMSON

OUR ASTRONOMICAL COLUMN

Change of Colour in a Star.—Dr. Klein of Cologne first directed attention to a periodical change of colour in the star α Ursæ Majoris, from yellow to an intense fiery red, and estimated the duration of the period to be about five weeks. In a communication to the *Astronomische Nachrichten*, he gives observations by Herr Weber from August 22, 1876, to October 24, which support his inference. Thus on September 5 and October 10 the star was considered "stark feuerroth" and "feuerroth, tief," while on August 22 and October 24, it was noted "weissgelb" and "gelb, schwach blaulich" respectively: from September 5 to October 10 is a period of thirty-five days, confirming the earlier estimation by Dr. Klein. Herr Weber observed with a Steinheil achromatic of 2⅝ inches aperture, and 3½ feet focal length with a power of 90. Probably since the suspicion of a regular change of colour was made known, the star has engaged the attention of other amateurs, who may be able to add something to the evidence pro or con.

New Double Stars.—Mr. Ormond Stone, Director of the Observatory, Cincinnati, has circulated a list of fifty double stars, varying in distance from 0″·8 to 8″·0, which are assumed to be new, and which have been recently found by Mr. Howe with the eleven-inch refractor; the whole are included between 8° and 40° south declination. Positions are given for 1880, with estimated angles and distances, and the magnitudes of the components. Since the number of rapidly-revolving double-stars is probably much greater than at present known, it appears very desirable that micrometrical measures of objects newly discovered should be at once placed upon record, in place of merely estimated angles, which form no satisfactory starting-points for the calculation of orbits.

The Binary Star η Cassiopeæ.—Dr. Gruber, of Buda-Pesth, has investigated elements of this binary, from normal position-angles formed with the aid of Duner's orbit. His figures agree as nearly as can be expected in such a case with those obtained by the careful calculation of Doberck. With the value of annual parallax obtained by O. Struve, viz., 0″·154, we find—

	Gruber.	Doberck.
Mass of the system	4·632 ...	5·256
Semi-axis major	56·097 ...	63·831

The sun's mass is taken for unity, and the semi-axis major is expressed in mean distances of the earth from the sun. Dr. Gruber's period is 195¼ years.

In the only two cases which we are at present able to compare with that of η Cassiopeæ we have for α Centauri, mass of system = 2·2 sun-masses, while for 70 Ophiuchi the similar value is 3·1.

The Mass of Neptune.—It is understood that M. Leverrier, from his final researches on the motion of Uranus, obtains a sensibly larger value for the mass of Neptune than has been assigned by Prof. Newcomb, and one approximating to that which was inferred many years since from Mr. Lassell's direct measures of the distances of the satellite.

The Nautical Almanac for 1880 has been published during the last week. The ephemeris of the planet Saturn, which since the appearance of the almanac in its improved form has hitherto been founded upon Bouvard's Tables, is computed from heliocentric plans communicated by M. Leverrier in advance of the publication of his new tables in vol. xii. of the *Annales* of the Observatory of Paris; the number of standard stars has been increased from 149 to 197, and in extending Damoiseau's Tables of Jupiter's satellites, certain corrections supplied by Prof. Adams have been introduced.

The impression of the *Nautical Almanac* now considerably

METEOROLOGICAL NOTES

Accelerated Transmission of Weather Maps.—The *New York Herald* of November 7 publishes a map of the weather of that morning, exhibiting the lines of atmospheric pressures and of the temperatures over the United States. The meteorological charting which was finished at the Central Office in Washington at 10 A.M. was immediately transmitted from Washington in *fac-simile* by telegraph to Philadelphia, where it was received at 10.30 A.M. It was shortly thereafter published in the supplement of the *New York Herald* of the same day, being the first occasion on which such telegraphic charting had appeared in any newspaper. The fact of telegraphing and printing such charts solves one of the greatest difficulties of exchanges of Weather Reports. It may now be regarded as only a question of time when the more important newspapers of our British large towns will be in a position to present their readers every morning with a chart of the weather as existing only two or three hours before going to press; and indeed it will not be till this result be effected that the practical utility of weather warnings will be properly developed, owing to our close proximity to the Atlantic and the rate at which our weather-changes pass to the eastward.

Great Storm of Wind at Sydney.—Mr. Russell, the Government astronomer at Sydney, reports that during a heavy storm of wind which occurred in that part of Australia on Sunday, September 10, the wind, in a gust lasting one or two minutes, attained the extraordinary rate of velocity of 153 miles per hour, as ascertained by Robinson's cup anemometer; and that during the twelve minutes, from 12.18 to 12.30 A.M. 22¼ miles of wind passed the Observatory, being at the rate of 112 miles per hour. This extraordinary recorded velocity may be regarded as a new contribution to meteorological observation, and we look with much interest to the description which will doubtless be given of the method by which it was determined. It scarcely admits of a doubt that the maximum velocity or force of the wind that occurs in great storms is frequently much understated.

The Temperature of the Northern part of the Atlantic.—An important contribution to the physics of the North Atlantic appears in the November number of *Petermann's Geogr. Mittheilungen*, in a paper by Prof. Mohn on the temperature of the sea beween Norway, Scotland, Iceland, and Spitzbergen The material employed in the discussion consists of the observations collected by the Norwegian Meteorological Institute from the lighthouses on the coast of Norway and from Norwegian ships, and the observations published by the Scottish Meteorological Society from their stations in Scotland, Farö, and Iceland—the observing stations, exclusive of the ships, numbering twenty-two. At places where observations only for two or three years are available, they are reduced to the longer period of the nearest station by the process of differentiation, with the result that virtually the averages are all good and fairly comparable with each other. The results are represented on seven charts, well executed in colours, showing by six distinct shades, as well as by isothermal lines, the distribution of temperature over this portion of the Atlantic for each set of two months and for the year, and the changes in the positions of the same temperatures from season to season. The outstanding feature of the charts is a strongly marked warm thermal axis, taking a north-easterly direction about 150 miles to westward of Scotland and Norway, extending even beyond the North Cape. Along this line of warm water temperatures are considerably higher than elsewhere in the same latitude. On the July-August chart, however, the warm axis approaches much nearer to the coast of Norway, and extends only from off the Naze to about lat. 66°. From June to September the North Sea is coldest on the Scottish coast and warmest

In other words, during the hottest months the influence of the heated land is powerfully felt, but during the other two-thirds of the year the peculiar distribution of the temperature is determined by the strong south-westerly winds and current of the Atlantic. This influence of the Atlantic on the temperature of Western Europe is enormous, the thermic anomaly for January being estimated by Prof. Mohn to be 10°·8 in the interior of Norway, 25°·2 in Scotland, 32°·4 in the north-west of Iceland, while in Lofoten it amounts to 41°·4. In May–June and in a slight degree in July–August, a large extent of cold water appears as if thrust out from the Arctic Sea west of Jan Mayen to the south-eastwards as far as Farö, deflecting and crowding together the whole of the isothermals over this region in a most remarkable manner. This is a point which well deserves the most careful investigation, not merely from its evident importance to the fisheries of this part of the Atlantic, but also from its meteorological significance, it being in May and June that atmospheric pressure reaches its annual maximum, northerly and easterly winds their greatest predominance, the weather becomes brightest and clearest, and the rainfall sinks to its annual minimum over the extreme north-west of Europe. An instructive comparison is also made between the temperature of the sea and that of the air, and a valuable discussion is added of the observations made at different depths of the sea between Iceland and Norway; but for these and other interesting points we must refer to the paper itself.

BIOLOGICAL NOTES

NEW FRESH-WATER RHIZOPODS.—For many years the small group known as Actinophrys, first accurately described by Ehrenberg, remained somewhat isolated, distinguished among unicellular forms by its nearly constant spherical form, and the persistence of its straight radiating processes or "pseudopodia." But in recent years a whole series of organisms has been described, and has attained sufficient prominence to constitute, with Actinophrys, an order denominated Heliozoa. Many interesting papers have appeared in the *Archiv fur mikroskopische Anatomie* on these organisms, contributed by F. Hertwig, Lesser, Cienkowski, Greeff, and others; and in our own country Mr. W. Archer has been the most active and successful student of the Heliozoa, his papers having been principally published in the *Quarterly Journal of Microscopical Science*. From these one derives an idea of these animalcules as being the most complex of the free forms which possess pseudopodia, and are at the same time unicellular; they are neither multicellular and differentiated like the Radiolaria, nor organised like the ciliated Infusoria. While a few forms, as Actinophrys, are quite devoid of skeleton, most of them possess certain hard parts, consisting, it may be, of a single solid and globular piece, but in other cases of very minute rod-shaped spicules, sometimes siliceous, sometimes easily soluble. These are either disposed so as to invest the main body of the organism more or less closely, or radially, projecting as spines. When food is taken, these minute hard parts can be pushed aside to allow access to the central body-mass; and the same occurs when indigestible material is thrust out. Locomotion is usually very slow; most Heliozoans move by balancing themselves on the tips of their pseudopodia, and thus very gradually rolling onwards. Multiplication of the organisms is effected by division, either simple, or occurring after encystation. Some forms are remarkable for containing a great abundance of chlorophyll granules.

RE-ARRANGEMENT OF THE ORDERS OF ENDOGENS.—At a recent meeting of the Linnean Society of London, Mr. Bentham proposed an entirely new arrangement of the orders of Endogens, which he believes to be more in accordance with their genetic present in use. He proposes to classify Endogens under four series, viz., 1. EPIGYNÆ; flowers with a double usually petaloid perianth; ovary usually inferior syncarpous. 2. CORONARIEÆ; flowers with a double usually petaloid perianth; ovary superior, almost always syncarpous. 3. NUDIFLORÆ; flowers usually achlamydeous, or with a dry perianth; ovary mostly apocarpous; and 4. GLUMALES; perianth replaced by membranous scales (paleas or lodicules); ovary always uniovular. The orders are arranged thus in the four series:—in the first, Hydrocharideæ, Scitamineæ (including Musaceæ, Cannaceæ, &c.), Orchideæ, Burmanniaceæ, Irideæ, Amaryllideæ (including Hæmodoraceæ), Taccaceæ, Dioscorideæ, and Bromeliaceæ (?); to the second, Roxburghiaceæ, Liliaceæ (including Melanthaceæ, Smilaceæ, &c.), Pontederiaceæ, Philydraceæ, Xyrideæ, Commelynaceæ, Junceæ, and Palmæ; to the third, Pandaneæ, Aroideæ, Typhaceæ, Lemnaceæ, Naiades (including Juncagineæ), and Alismaceæ (?); and to the fourth, Eriocauleæ, Centrolepideæ, Restiaceæ, Cyperaceæ, and Gramineæ.

THE SENSATION OF SOUND.—At a recent meeting of the Vienna Academy a paper was communicated by Dr. Isidor Hein "On the Relations between Perceptions of Touch and of Hearing." His conclusions are these:—1. The sound produced by striking a solid body is always accompanied by a sensation of touch, which, like the sound, differs according to the nature of the body. If the sound is different in different parts of a body, there goes along with the variation of the sound, a variation in the touch-sensation; and if the surface be divided into several sections according to differences in sound, a congruent division may be made on the basis of touch. 2. On bringing a struck body towards a reflecting wall, the sound and touch-perceptions show similar variations. 3. To the touch-perception in question correspond vibratory motions of the exterior body, produced even with the weakest striking, whereas sound only begins to be perceived with impacts of a certain intensity. 4. The sense of touch is capable of perceiving vibrations and comparing the differences of these. It brings hereby to consciousness, a special quality of touch-sensation, which is to be distinguished from sensation of pressure. 5. This distinguishing power of the organ of touch, not sufficiently appreciated hitherto, offers practical medicine a peculiar mode of investigation, which greatly enlarges the doctrine of the physical symptoms of the human organism, and for which the author suggests the (German) name of "Erschutterungs-palpation."

THE ABSORPTION OF ORGANIC MATTER BY PLANTS.—In a communication from Prof. Calderon, of the Institute of Las Palmas, Canary Isles, he contests the ordinary view that the nitrogen of the tissues of plants is derived entirely from the nitrates and ammoniacal salts absorbed through the roots. He does not, however, adopt the old theory that the source is the free nitrogen of the atmosphere, but rather the nitrogenous organic matter which is always floating in the air. The nutrition of plants he divides into three classes: *necrophagous*, the absorption of dead organic matter in various stages of decomposition; *plasmophagous*, the assimilation of living organic matter without elimination, or distinction of any kind between useful and useless substances, such as the nutrition of parasites; and *biophagous*, the absorption of living organisms, such as that known in the case of insectivorous plants. A further illustration of the latter kind of nutrition is, according to Prof. Calderon, furnished by all plants provided with viscid hairs or a glutinous excretion, the object of which is the detention and destruction of small insects. To prove the importance of the nitrogenous substances floating in the air to the life of plants, he deprived air of all organic matter in the mode described by Prof. Tyndall, and subjected lichens to the access only of this filtered air and of distilled water, when he found all their physiological func-

NOTES

THE Kew Committee have appointed Mr. G. N. Whipple, B.Sc., Superintendent of the Observatory. Mr. Whipple's connection with the establishment is of nearly nineteen years standing, he having entered it in January, 1858.

DR. PETERMANN has sent us a map in which he has embodied the discoveries of the English Arctic Expedition. He appears still to maintain his well-known hypothesis of the continuation of the north coast of Greenland towards and beyond the North Pole. He draws the line of the visible horizon of the English Expedition at about fifty nautical miles north of Grant Land, its furthest north point being the 84th deg. of lat., and remarks that north of this line may be either land or sea. Of course no one can contradict this. He has, however, restored President's Land in rather a remarkable position, identifying it apparently with Beaumont's Cape Britannia, to the north of Beaumont's furthest point on the north coast of Greenland. The map will be found a very useful one in studying the route of the expedition, especially as compared with that of the *Polaris*.

CAPT. NARES and the other Arctic officers have been entertained by the Greenwich cadets and by the Royal Naval Club at Portsmouth. Capt. Nares stated that when the whole story of the efforts of the expedition is published, it will be seen that better work could not have been done.

THE constituents of fodder-remains of rhinoceroses and mammoths in Northern Siberia have been examined by several observers, and the conclusion arrived at that these animals lived in the places where their frozen bodies have been found, on plants which are still to be met with in Northern Siberia. New ground for this opinion has been furnished by M. Schmalhausen to the St. Petersburg Academy, who has examined microscopically the constituents of a mass of dark-brown matter extracted from hollows in the teeth of a rhinoceros in the Irkutski Museum. That this was truly the remains of fodder of the animal seemed clear from the appearance and the macerated character of the vegetable substance, of which only the woody and cuticular parts showed a more or less distinct structure. The greater portion of the piece consisted of leaf-remains, with here and there a fragment of stem. For the most part the stem and leaf-fragments were those of monocotyledonous plants, probably of Gramineæ; there were also, in less quantity, leaf-fragments of dicotyledonous plants. Besides leaf-shreds of Coniferæ, there were woody pieces which indicated the existence of Picea (Obovata ?), Abies (Sibiria ?), Larix (Sibirica ?), Gnetaceæ, Betulaceæ, and Salicineæ. If it is scarcely possible to determine certainly the species of a plant merely from some of the wood received in the state indicated, and from the structure of the leaf epidermis, it yet seems unquestionable that these remains must be referred to northern plants and to such as are still partly found in the high north.

MR. COXWELL writing to the *Daily News* in reference to Arctic ballooning, maintains that the ordinary practice of ballooning would be quite unsuitable for the conditions found in the Arctic regions.

M. MORITZ, director of the Tiflis Observatory, makes an interesting communication on the results of an examination of the magnetic instruments there last July by Prof. Smirnoff, of Kasan, who has been engaged during the last six years travelling through to determine the elements of terrestrial magnetism. The instruments employed by Prof. Smirnoff, which cost 300 roubles, were all verified at Kew, and are furnished with microscopes and all the other accessories of the English system. The compass has three needles (No. 4, No. 3, and No. 16), four inches in length, and the mean of the readings of the three needles is the true

structed according to the old method of Gambey, which are now generally looked upon as inferior instruments. They cost respectively only 165 and 40 roubles. The results of a very careful comparison are these:—Assuming the mean of the indications of the three Kew needles as the true inclination the errors of the instruments were, Kew No. 4, − 0′·25; No. 3, + 2′·45; and No. 16, − 2′·22; the error of the large Gambey being + 0′·30, and of the small Gambey − 0′·09. M. Moritz remarks that the microscope and detached circle on which the readings are made, and which add so greatly to the price of the English compass, appear to add nothing to the precision with which the inclination is determined, facilities for minute readings of the compass being made counting but little, it being the form of the pivots of the physical axis of the needle which stamps its character on the instrument.

"ON Some Insect Deformities," by Dr. Hermann A. Hagen, is the title of No. 9, vol. ii., of the *Memoirs* of the Museum of Comparative Zoology, Harvard College, Cambridge, U.S.

WE have received from Herr Schmidt, publisher, Zürich, Dr. Hermann Berge's "Beiträge zur Entwicklungsgeschichte von *Bryophyllum* Calycinum," and Dr. Gustav Schoch's "Die Schweizerischen Orthopteren."

THE following German publications have been sent us by Messrs. Williams and Norgate:—"Ueber die Zugstrassen der Vögel," by J. A. Palmén, of Helsingfors; "Grundzüge der Mikrophotographie," by Max Hauer; "Sammlung wissenschaftlicher Vorträge von Prof. Wilhelm Förster;" "Die Darwin'schen Theorien und ihre Stellung zur Philosophie, Religion, und Moral," by Rudolf Schmid.

THE Goldsmiths' Company, whose donation to the Chemical Society we noted last week, have voted 500*l*. in aid of the fund for extending Edinburgh University buildings. It is stated that this Company spends annually 6,000*l*. for educational purposes alone. We wish the other City Companies would follow such a good example.

THE following were elected office-bearers of the Royal Society of Edinburgh on Monday last:—President, Sir William Thomson; Vice-Presidents, Rev. Dr. Lindsay Alexander, Bishop Cotterill, Sir Alexander Grant, Prof. Kelland, Lord Neaves, and David Stevenson; General Secretary, Prof. Balfour; Secretaries to Ordinary Meetings, Professors Tait and Turner; Treasurer, David Smith; Curator of Library and Museum, Prof. Maclagan; Members of Council, Prof. Crum Brown, Dr. James Bryce, Alexander Buchan, Dr. Matthews Duncan, Dr. A. Fleming, Dr. T. Harvey, D. Milne Home, Prof. McKendrick, Dr. C. Morehead, Sir C. Wyville Thomson, Dr. R. H. Traquair, and Dr. Robert Wyld.

THE next meeting of the French Association for the Advancement of Science will take place, as we have already intimated, at Havre in the end of August, 1877, under the presidency of Dr. Broca. A local committee has been already formed at Havre under the presidency of M. Mazurier, the mayor. At the first meeting M. Gariel, the secretary of the committee, suggested many useful and interesting experiments to be made in the Seine or the sea. Special efforts will be made to procure a large attendance of English *savants* and members of the British Association. It is reported that a special deputation will be sent to the Dublin meeting of the British Association. The place of meeting for 1878 has not yet been determined upon, but it will probably be Versailles or Paris.

THE *Times* of Monday contains a journal kept by the Rev. Mr. Lawes during a voyage from Port Moresby to China Straits, At Hood's Bay they sailed up a considerable river, and near the coast found a large village, regularly laid out in streets and squares, scrupulously clean, with gardens and carefully cultivated flowers. Canoes of large size and excellent make they saw being hewed out with stone hatchets. At a lagoon at Cape Rodney a regular lake village was found, the lagoon leading up to a considerable river. Near Table Point a large canoe "manned" by at least twenty-one women, came alongside; it is reported at Port Moresby, and all along the coast, that there is a village of women somewhere near Amazon Bay.

At the last meeting of the French Geographical Society, the president, M. Malte Brun, intimated that the Council General of the Seine had voted a sum of 2,000 francs to assist M. Largeau in his exploration of the Sahara. M. Largeau left on November 19 for Algiers, whence he will proceed to Constantine, Tuggurth, and Central Sahara. The subscription on his behalf is proceeding. The Geographical Council of Lyons has voted a small subsidy of 12*l.*, and the Municipal Council of Lyons will send him, within a very few days, a considerable donation. M. Melidin, a rich landed gentleman, has offered to the Society to maintain during one year any traveller approved by the Society. The offer was accepted with thanks. On December 20 the general secretary will deliver a lecture on "The Progress of Geography during 1876," and on the following day the annual banquet will take place at the Grand Hotel.

At the Geographical Society on Monday night papers were read on the results of Col. Gordon's expedition in Central Africa, from General Stone, the Rev. E. J. Davis, and Signor Gessi. Sir Rutherford Alcock announced the death of an African missionary, Mr. Redman, who, by his explorations, had materially helped subsequent travellers, and who first suggested that there was a great system of lakes in Central Africa.

A great extension of the medical department of the University of Heidelberg has been in progress for some time. Large additions to the Medical School and the Hospital attached to it have been made, and when completed, as it will be shortly, this institution will be one of the most complete in Europe. Every provision has been made for scientific investigation in connection with the healing art in all its departments.

The *Archiv für Anthropologie* (ix. 173) contains a paper by Herr L. Lindenschmidt, in which he pronounces his conviction that the drawings upon the fossil bones found in the Thayingen Cave are spurious and the result of intentional deception. These drawings, which represent a bear, a fox, and a stag, were generally admired in scientific circles in 1874 (when they were found) as being amongst the most perfect specimens of the kind; they also led to the supposition of the highly-civilised state of the ancient cave inhabitants. Herr Lindenschmidt produces evidence to the effect that precisely the same drawings are contained in a little work by Leutemann, "Die Thiergärten und Menagerien mit Ihren Insassen," which was published in 1868, *i.e.* six years before the discovery of the cave near Thayingen. As the work in question had a very wide circulation in Germany the inference drawn is obvious.

A notice in the *Ostsee Zeitung* accounts for the frequent deficiencies in the aroma of foreign cigars by announcing that from Guben whole waggon-loads of dried cherry-leaves are weekly exported for the manufacture of "tobacco."

A successful *soirée* of the Manchester Scientific Students' Association was held last Friday, when Prof. Williamson gave an address on Insectivorous Plants.

A very fine new university building has been erected at Kiel, one marked peculiarity of which is that it has no "carcer," or prison, which hitherto, it seems, has been an invariable appendage to German universities.

There met in Berlin, a few days ago, a German Government Commission whose business it is to look after the moors and marshes of Germany. They resolved to establish an experimental station at Bremen, to be opened on April 1 next year, drew up a plan for obtaining statistics and a topography of moors, and made arrangements for the complete canalisation of the moors in the Duchy of Bremen. The labours of the Commission will include the whole of Germany.

The directors of the Swedish Government railways have turned their special attention to the frequent occurrence of colour-blindness amongst their engine-drivers and other officials. Prof. Holmgren has lately examined the whole staff of the Upsala-Gefle Railway, and amongst the 266 persons examined has found no less than eighteen who suffered from this defect, and who therefore were utterly useless and unfit for railway service. This investigation proves that cases of colour-blindness are far more frequent than is generally supposed, and that our railway companies would do well to follow the example of the Swedish State railways.

The *Kölnische Zeitung* of the 14th inst. declares that the recent sudden cold was a perfectly abnormal meteorological phenomenon, and all the more so since it did not only visit a part but nearly the whole of Europe. Reports of heavy snowstorms have come from the whole of North Germany, Austria, Servia, and Roumania, and the temperature had fallen below freezing in all these countries as well as in Western France, Italy as far south as Rome, and the whole of European Turkey. In Hungary the cold reached 13° C. Violent gales were raging in the Black Sea, the Adriatic, and the Baltic. In another article, dated from the Teutoburg forest, the paper reports that the whole of that district is snowed up, and a valuable crop of vegetables, beetroot, &c., has been destroyed by the cold.

A Mons. Ménier, of Bordeaux, has invented a new contrivance for the steering of balloons. The mechanism is placed behind the car, and by a clever arrangement of network acts upon a belt which encircles the body of the balloon, extending about four or five degrees above and below a horizontal plane through its centre—its equator, so to say. The rudder is plane, and can be used as a sail. The balloons are said to move obliquely upwards and downwards and also sideways, according to the position of the rudder. The sideway motion is very likely facilitated by changing the position of ballast. One circumstance, which may be of special practical use, is that a balloon provided with this new apparatus, when falling to the ground, can be made to touch the earth's surface very obliquely and thus avoid any sudden shock, and at the same time facilitate a safe anchoring.

Herr Edward Trewendt, publisher, Breslau, has issued the prospectus of a New Encyclopædia of the Natural Sciences, which will include all departments of science. The first part will appear on January 1, 1878.

More than 18,000 francs have been already collected for the erection of Arago's statue at Perpignan.

The additions to the Zoological Society's Gardens during the past week include a Bonnet Monkey (*Macacus radiatus*) from India, presented by Mr. E. F. Mathews; a Slender-billed Cockatoo (*Licmetis tenuirostris*) from South Australia, presented by Mr. Stevens; a Gannet (*Sula bassana*), European, presented by Mr. R. H. W. Leach; a Peregrine Falcon (*Falco peregrinus*), captured at sea, presented by Mr. A. Whyte; a Grivet Monkey (*Cercopithecus griseo-viridis*) from Nubia, an Indian Leopard (*Felis pardus*) from India, a Hooded Crane (*Grus monachus*) from Japan, a Globose Curassow (*Crax globicera*) from Central America, deposited; an Indian Muntjac (*Cervulus muntjac*), a Japanese Deer (*Cervus sika*), born in the Gardens.

SCIENTIFIC SERIALS

Morphologisches Jahrbuch, vol. ii. Part 2.—On the structure of the toes of Batrachia, &c., by Dr. F. Leydig (32 pages).—On the valvular apparatus in the conus arteriosus of Selachians and Ganoids, by Dr. Stöhr.—Contribution to the anatomy and histology of Asteroids and Ophiuroids, by Wichard Lange (46 pages, 3 plates).

REICHERT and Du Bois Reymond's *Archiv*, September, 1876.—Studies on animal heat, Part 3 (conclusion), by Dr. A. Adamkiewicz.—Contribution to the theory of the growth of bone, by Dr. L. Lotze.—On the negative variation of the muscular current during contraction, Part 3 (conclusion), by Du Bois Reymond.

Archiv für mikroskopische Anatomie, vol. xiii. Part 1, July, 1876.—Rhizopod studies, No. vi., by F. E. Schulze.—On the anatomy and histology of the Coccidæ, by E. L. Mark.—Studies of the development of Gastropods, by N. Bobretzky (75 pages), with 6 plates illustrating the development of *Nassa mutabilis*, Natica, and Fusus.—On the hypothesis of discharge and the motor end plates, by W. Krause.

Bulletin de l'Académie Impériale des Sciences de St. Pétersbourg, t. xxii., No. 2.—This part contains the following papers of interest :—Diagnoses plantarum novarum Japoniae et Mandshuriae, decas xx. (continued from last vol.), by C. J. Maximovicz.—On the plants of the bear period found in the deposits of the Ogour river, a tributary to the Jenissei, in Siberia, by J. Schmalhausen.—Preliminary communication by the same, on a microscopical examination of the food-remains of Siberian fossil rhinoceros, viz., *Rhinoceros antiquitatis seu tichorinus*.—On the supposed satellite of Procyon (α Canis min.), by O. Struve. The other contents are only of archæological and philological interest.

SOCIETIES AND ACADEMIES

LONDON

Linnean Society, November 16.—Prof. Allman, president, in the chair.—Messrs. J. C. Oman, R. H. Peck, and D. G. Rutherford were duly elected fellows.—Mr. H. N. Moseley, of H.M.S. *Challenger*, read a paper on the flora of Marion Island. This island possesses considerable interest from its isolation and being within the Antarctic drift. It is about 1,000 miles from the African Continent, 450 from the Crozets, 1,200 from the desolate Kerguelen Island, above 2,000 from Tristan D'Acunha, and 4,500 from the Falklands, to which, nevertheless, its flora appears related. It is of volcanic origin and snowclad. The rocks at half-tide are covered with *Darvilea utilis*, above high tide *Tillæa moschata* is found in abundance, and beyond the beach a swampy peaty soil covers the rocks, where there is a thick growth of herbage ; this is principally composed of species of *Acæna*, *Azorella*, and *Festuca*, the first of these three being the most abundant plant on the island, though the latter grass is by no means scarce. The cabbage-like plant *Pringlea antiscorbutica* is less profuse than at Kerguelen's Land. Some of the ranunculus group are met with at water pools near the sea ; four kinds of ferns were obtained, *Lomaria Alpina* being the most numerous. Lichens are scarce, but mosses in plenty form yellow patches, which stand out conspicuously midst the green vegetation, which rises to an altitude of probably 2,000 feet. From the occurrence of *Pringlea* on Marion Island, the Crozets, and Kerguelen Island, and the existence of fossil tree-trunks on the two latter, the author surmises an ancient land connection between them.—A memoir on the birds collected by Prof. Steere (U.S. Michigan) in the Philippine Archipelago was read by Mr. R. Bowdler Sharpe, and copious coloured drawings of the new and rare forms exhibited and commented on. Although it is but lately that Lord Tweeddale's (President Zool. Soc.) remarkable monograph on the Philippine birds was published, with immense additions to the avifauna, yet Steere's collection has yielded over sixty hitherto unknown species. Many novelties may therefore still be expected as further exploration proceeds. The recorded species of birds from the Philippines at the present now amount to 285.—A letter containing observations on the American Grasshopper (*Caloptenus femur-rubrum*), with remarks on the same by Mr. Frederick Smith, was noticed.—Mr. Moseley exhibited some insular floral collections in illustration of his paper and of the various parts touched at by the *Challenger*. He also called attention to a series of volumes and pamphlets, &c., on natural history obtained by him in Japan.

Zoological Society, November 21.—Prof. Flowers, F.R.S., vice-president, in the chair. The Secretary read a report on the additions that had been made to the Society's Menagerie during the month of October.—Mr. Sclater exhibited and made remarks on the skin of a young rhinoceros (*R. sondaicus*), belonging to Mr. W. Jamrach, which had been captured in the Sunderbunds, near Calcutta, in May last.—The Secretary exhibited on behalf of Mr. Andrew Anderson, a coloured drawing of a specimen of *Emys hamiltoni*, lately captured at Futtehgurh (Ganges). The occurrence of this *Emys*, chiefly confined to Lower Bengal, so far west as Futtehgurh, was considered as of much interest.—A letter was read from Count T. Salvadori, containing remarks on some of the birds mentioned by Signor D'Albertis, as seen by him during his first excursion up the Fly River.—A communication was read from Mr. G. B. Sowerby, jun., containing descriptions of six new species of shells, from the collections of the Marchioness Paulucci and Dr. Prevost.—Mr. Edward R. Alston read a paper containing the descriptions of two new species of *Hesperomys* from Central America, which he proposed to call respectively *Hesperomys teguina* and *H. couesi*.—A paper was read by Prof. Garrod, F.R.S., on the Chinese Deer, named *Lophotragus michianus*, by Mr. Swinhoe, in which he showed that the species so called was identical with *Elaphodus cephalophus* (A. Milne Edwards), obtained by Père David in Moupin. The close affinity between the genera *Elaphodus* and *Cervulus* was demonstrated, the latter differing little more than in the possession of frontal cutaneous glands not found in the former.—Mr. Arthur G. Butler read a paper containing descriptions of new species of Lepidoptera, from New Guinea, with a notice of a new genus.—A communication was read from Dr. J. S. Bowerbank, being the eighth of his series of "Contributions to a General History of the Spongiadæ."

Meteorological Society, November 15.—Mr. H. S. Eaton, M.A., president, in the chair.—Messrs. R. A. Allison, John Evans, F.R.S., Dr. W. Marcet, F.R.S., Rev. T. G. P. Pope, and Mr. G. Washington were elected fellows.—The following papers were read :—Results of meteorological observations made at Rossinière, Canton Vaud, Switzerland, during 1874 and 1875, by Mr. William Marriott. Rossinière is situated in a valley running north-east and south-west, about three quarters of a mile broad, the mountains on the north being 3,000 to 4,000 feet above the valley of the Sarine, and those on the south, 1,000 to 3,000 feet. The valley is shut in at either end by a gorge, that on the east being about one mile, and that on the west about two miles distant. The observations were all taken by Col. M. F. Ward, F.R.A.S. The mean temperature, as deduced from the mean of the maximum and minimum readings, was 43°·4 for 1874, and 43°·5 for 1875. The monthly means ranged from 20°·0 for December, 1874, and 20°·5 for December, 1875, to 64°·9 for July, 1874. The highest temperature in 1874 was 89° on July 3, and 1875, 85° on August 18 ; the lowest in 1874 was − 4° on December 24, and in 1875 − 7° on January 1. Owing to the situation of Rossinière, the prevailing winds are those from north-east and south-west. In the winter months the air is for the most part calm, and it is owing to this absence of wind that the intense cold is not so severely felt as it would otherwise be. The total rainfall for 1874 was 54·282 inches, and for 1875, 55·870 inches. The months of greatest rainfall are July and November, and those of the least February and March. Thunderstorms occur frequently from May to August, as many as five being sometimes recorded in one day. The number of thunderstorms observed in 1874 was forty-five, and in 1875, forty-three. No thunder was heard or lightning seen in the months of December to March.—The climate of Fiji, by Mr. R. C. Holmes. This paper contains the results of meteorological observations taken at Delanasau, Bay of Islands, north coast of the province of Bua, Fiji, during the five years ending 1875. The average annual mean temperature is 79°·1. The highest temperature recorded was 97°·7 on January 12, 1871, and the lowest 58°·5 on August 20, 1875, the extreme range in the five years being 39°·2. The average annual rainfall is 124·15 inches, and the number of rainy days 170. The greatest fall in 24 hours was 14·95 inches, which occurred on March 19, 1871. After describing somewhat fully the chief characteristics of the months and seasons, hurricanes and storms, earthquakes, waterspouts, &c., the author concludes with the question, "Is the climate of Fiji a healthy one?" In reply he says that, considered as a tropical country, an affirmative answer may be given without hesitation. Those fatal diseases so common in tropical countries, fevers of various kinds, cholera, and liver complaints, are almost unknown. This is owing partly to the geographical position of the group, lying in the region of the trade winds, so that it enjoys almost perpetual breezes, calms being rare, and the islands so small that the sea-breeze from all directions can penetrate into every corner.—Notes on some remarkable errors in thermometers recorded at Sydney Observatory, 1876, by Mr. H. C. Russell, F.R.A.S. For upwards of five years the same hygrometer has been in use at the Observatory; the dry bulb is small, only 0·3 inches in diameter, and the instrument up to February 26 had always given very satisfactory readings, tested by those of a standard which hangs only 3 inches from it; the difference in the readings was usually 0°·2 to 0°·3. On that day the maximum shade temperature rose to 96°·4 about noon; at 3 P.M. the dry-bulb and standard read 83°·7, and at 9 P.M., 68°·9 and 69°·0. Next morning they read 69°·6 and 69°·8; as this was Sunday, they were not read again until 9 A.M. on the 28th, when the dry bulb read 87°·3, and the standard 64°·9, showing a difference of 22°·4. It was at once thought that the glass had cracked and let in the air, but as no crack could be seen after careful examination, it was determined to continue the readings. The author had always found before that if a thermometer cracks in the bulb, the mercury rises till the tube is full, and he expected it would be so in this case, though he could see no crack. The result, however, was that the difference steadily decreased, at first at the rate of 1° each day, and in thirty-five days the difference had fallen to less than 0°·5, or almost to its normal condition. Between April 7 and 17, it rose again, then fell; on May 3, and again on the 7th, sudden rises took place, since then the difference has been diminishing, except a slight rise on May 21 and 22. When very closely examined with the microscope, a very small piece of coloured glass is to be seen in the bulb, as if lead had been reduced by the blowpipe, and on one side of the bulb a mark is visible, as if there was a minute quantity of water between the mercury and the glass at one spot.

PARIS

Academy of Sciences, November 20.—Vice-Admiral Paris in the chair.—The following papers were read:—Meridian observations of small planets made at the Greenwich and Paris observatories during the third trimestre of 1876, communicated by M. Leverrier.—Tables of the planet Uranus, based on comparison of theory with observations, by M. Leverrier.—On the physical and chemical properties of ruthenium, by MM. H. Sainte-Claire Deville and Debray.—New researches on the chemical phenomena produced by electricity of tension, by M. Berthelot. He studies the relations of the reactions to sign and tension of the electricity.—On the composition of some phosphites, by M. Wurtz. Phosphite of calcium, neutral and acid phosphites of barium.—On the quantity of rainfall at Rome during fifty years, 1825 to 1874, by P. Secchi. The yearly maximum is in the end of October and beginning of November. No relation was perceptible between the quantity of rain and the sun-spots. The great rain-periods at Rome coincided with floods of the lake of Fucino, 100 kilos. distant.—Organisation of a new meteorological observatory on Monte-Cavo; meteorological observations near Rome, by P. Secchi.—On the modifications of elæomargaric acid produced by light and heat, by M. Cloez.—On the phenomenon of the black drop, by M. André.—On a series of experiments with regard to the flow of water made at the reservoir of Furens, by M. Græff.—On exchange of gases in the tympanic cavity; physiological considerations and therapeutical applications, by M. Lœwenberg. In cases of obstruction of the Eustachian tube, causing deafness, the volume of gas in the tympanic cavity is diminished, and the membrane presses inwards. The author says this diminution must be due, not to absorption, but to exchange by diffusion, and he suggests as remedies—(1) the insufflation of air that has been inspired and expired four or five times; (2) the insufflation of hydrogen.—New observations on the cure of typhoid fever by parasiticide phenicated medication (phenic acid and phenate of ammonia, in draughts, and subcutaneous injection in large doses), by M. Declat.—The theory of systems of land-elevation, *à propos* of the system of Mont Seny, by M. Vezian.—Researches on the structure and the vitality of eggs of phylloxera, by M. Balbiani.—Remarks on M. Bouilland's observations regarding the effects produced by sulpho-carbonates, by M. Mouillefert.—Experiments on treatment of phylloxerised vines by phenic acid and alkaline phenates, by M. Rommier.—On the practical conditions of employment of insecticides to oppose phylloxera, by M. Delachanal.—Results obtained from the use of sulpho-car-

the employment of pyrites in treatment of vines affected with oïdium, by M. François.—On the gaseous movement in the radiometer, by M. Salet.—Experiments on the immersed radiometer, by M. de Fonvielle.—Absorbent powers of bodies for heat, by M. Aymonnet. The atomic absorbent power appears to be constant (1) for all simple bodies dissolved in the same medium; (2) for all simple bodies forming part of compounds of like chemical composition.—On a process of determination of alkaline sulphates, by M. Jean.—On the causes of error involved in the application of the law of mixtures of vapours, in the determination of their density, by MM. Troost and Hautefeuille.—On the saccharine matter contained in the petals of flowers, by M. Boussingault. This is considerable, amounting in some eighteen cases examined to an average of 4·88 per cent. in the undried flower.—On a process of testing wines for fuchsine, by M. Fordos.—On the investigation of rosolic acid in presence of fuchsine, by MM. Guyot and Bidaux.—New researches on the action of non-arsenical fuchsine introduced into the stomach and the blood, by MM. Feltz and Ritter.—On the action of iron in anæmia, by M. Hayem. It causes the globules to become charged with a larger amount of colouring matter, and this, not merely in the curable anæmic, but even in cachexia; where, the organism being exhausted, the production of red globules is almost entirely stopped.—Experiments on the pneumogastric and on nerves supposed to be inhibitory, by M. Onimus.—Researches on the urea of the blood, by M. Bernard.—On the power possessed by certain Acarians, with or without a mouth, of living without food during whole phases of their existence, and even their whole life, by M. Megnin.—On crystals of oxydulated iron presenting a singular deformation, by M. Friedel.—On the figures which are formed in superposed liquids, when a movement of rotation is imparted to them, by M. Bouquet de la Grye. These show some analogies to sun-spots. M. Faye added a few comments.—On some peculiarities of lightning, by M. Renon. Beaded lightning; purple or violet flashes; lightning in a near cloud without thunder; sound of thunder heard at 40 kilom. distance.—Observations of falling stars during the nights of November 12, 13, and 14, 1876, at Clermont Ferrand, by M. Gruey.—On the present state of volcanic phenomena of Carvassèra, by M. de Cigalla.

VIENNA

Imperial Academy of Sciences, October 12, 26.—The following among other papers were read:—The nerves of hair-covered skin, by M. Arnstein.—The germination of plant spores in its relation to light, by M. Leitgeb.—On spontaneous variations of blood-pressure, by M. Mayer.—On the action of chloroform and ether on breathing and circulation, by M. Knoll.—On some remarkable phenomena in Geissler tubes, by MM. Reitlinger and Urbanitzky.

THE YORKSHIRE LIAS

The Yorkshire Lias. By Ralph Tate and J. F. Blake. (London: Van Voorst, 1876.)

IT might at first sight seem a piece of presumption in one whose palæontological attainments are of the slenderest, and who knows no more of the Yorkshire Lias than has been picked up during a few days ramble along the coast, to attempt a criticism of a work conspicuous for elaborate palæontological research and rich in descriptive detail of the most minute and local character. But in forming an estimate of the work of a specialist the absence of minute special knowledge is in many cases far from being a disadvantage; the specialist always runs some risk of becoming engrossed with details, of looking upon them as the end and not as a means to something higher, of being "unable to see the wood for the trees," and ,as long as this risk exists, there is always a fair prospect that the remarks of an outsider, however inferior he may be in special attainments to the man whose work he is reviewing, may add something in breadth of view, and may suggest questions that have been overlooked in the task of collecting minute particulars. It is with this feeling that we attempt to give an account of the work before us, and to discuss some problems which its perusal has suggested to us; and we make the attempt all the more readily, because the authors have by no means in the multiplicity of their details lost sight of the broad questions which underlie and spring from them.

The opening chapter on the "General Range of Liassic Strata on the Continent and British Isles" would have been better for rather more copious references. The authors quoted may be well known to the mass of professional geologists, but if this book comes, as we feel sure it will, into the hands of workers of a more amateur class, mainly occupied with the geology of their own neighbourhood, but at the same time anxious to understand its relation to that of corresponding districts abroad, many of its readers will certainly be glad of directions where to find the papers of geologists not familiar to the world at large, and whose names they perhaps now meet with for the first time. This indifference to references is a growing and a very serious evil; take, for instance, such a book as Marcou's "Explication de la Carte Géologique de la Terre;" to attempt to give in 200 pages a complete account of the geology of the globe would be a hopeless task, but an outline no longer than this, abundantly furnished with references, would be a work whose value it would be difficult to overestimate; unluckily M. Marcou has fallen into the prevalent carelessness in this respect, and for every reference he has given, ought to have supplied fifty.

Chapter II. gives an account of the literature of the Yorkshire Lias; the abstracts of the various papers and works on the subject are admirable for point and conciseness, and the criticisms fair and just. In Chapter III. the range and general character of the Lias in Yorkshire are clearly sketched out.

The fourth chapter lands us in one of those disputes, unavoidable possibly in the present state of geological nomenclature, which have far too much the look of fighting about mere words to be altogether satisfactory. The point at issue is, where should the line be drawn between the Lias and the Inferior Oolite? In some cases the demarcation between the two formations is both lithologically and palæontologically so sharp as to leave no room for hesitation; but some sections show a group of beds in which fossils that occur in the Upper Lias are found side by side with others generally looked upon as characteristic of the Inferior Oolite. Here, then, was a fine battle-ground for the systematists, and here, accordingly, as in other analogous cases, much good ink and paper has been—shall we dare to say—wasted in discussing whether the problematical strata ought to be called Liassic or Oolitic. Dr. Wright maintains the first view, and the authors of the work before us lean to the second, the question being argued by both disputants on purely palæontological grounds; it turns partly upon the correct naming of certain Ammonites, hard to discriminate from one another, and possibly so closely allied that they ought to be looked upon as varieties rather than distinct species; it involves many points on which there is great difference of opinion, such as whether we ought to look mainly to the Cephalopoda or to the Conchifera in determining the relationship of the group; and after carefully considering what has been said on both sides, it certainly seems that it is one of those cases where the impartial bystander would find it so hard to make up his mind that he would be sorely tempted to resort to the unscientific method of "tossing up" to help him to a decision. Fortunately there is a better way out of the difficulty; we are not tied down, as the manner in which the question has been handled would seem to imply, to a single alternative. It is an easy thing to say that there shall be a Liassic group and an Oolitic group, and that of the rocks about the junction, what won't go into one shall be forced into the other, and by adopting this principle very neat tables of strata may be constructed. But if, as the group under consideration proves was the case, there was not a clean sweep of the Liassic forms of life before any Oolitic forms came in, but that to a certain extent the replacement was gradual, then wherever the record of the change in the least degree approaches completeness, beds will occur which contain a mixture of Liassic and Oolitic species, and consequently cannot be placed consistently under either of these heads. It is unfortunate for the symmetry of our classification that it is so, but being so, we must bear the evil as best we may. Perhaps the best way is to let each man *call* the beds in dispute Lias or Oolite as his fancy prompts him, but to be careful to bear in mind that the meaning they carry with them is this—that, when they occur, we have been lucky enough to have preserved a record, which at other spots either never existed or has been destroyed, of the rate at which changes in life that took place between two indistinctly outlined periods of the earth's history were brought about.

It would not, of course, be fair to blame Messrs. Tate and Blake, when they are writing a monograph on the Lias, for explaining what they mean by that term; but it would possibly have been more philosophical if they had looked upon their upper boundary as purely conventional, and noticed the beds above that line as of interest because they show a gradual passage from the life of the period with which they are specially concerned to the life of the period which followed it.

A dispute of a similar nature arises when we come to the boundary between the Lower and the Middle Lias. The tabulated lists of fossils given by our authors show in the Yorkshire area a marked palæontological break between the zones of *Ammonites oxynotus* and *A. Jamesoni*, and a similar break has been observed at a corresponding horizon both elsewhere in England and on the Continent. Here then German and a large number of English geologists draw the line. But a difficulty arises when we attempt to construct maps according to this classification; unfortunately the marked change in life is not accompanied by a corresponding change in the character of the rocks; the beds above and below the palæontological line are lithologically so much alike that it would be impossible to separate them on a map by the ordinary methods of geological surveying. Somewhat higher in the series, however, a change in lithological character, marked and sudden enough to allow of its being traced with considerable accuracy, does occur, and the field geologist, finding that he can separate on his map the rocks above and below this line, naturally draws a boundary here. Hence it arises that the subdivisions drawn on maps, such as those of the Geological Survey, do not coincide with those established from palæontological considerations. And no harm would follow from this if the lithological line always kept the same place in the series; we should merely have to bear in mind that the boundary laid down on the map was adopted out of sheer necessity, because it was the only line that could be traced, that it did not coincide with any great change in life, but that the palæontological break occurred at a certain distance below it. But in the case before us the hard sandstones and ironstones of the Middle Lias are notoriously irregular and uncertain, and if we make the Middle Lias begin where rocks like these —which can be separated on a map from the clays—first make their appearance, we shall place in the Lower Lias at Banbury beds which we call Middle Lias at Frodingham. In such a case, when the map-maker is driven to neglect or set at defiance palæontological boundaries, the right thing would seem to be that he should call his sub-divisions by names different from those used by the palæontologist; on the Survey maps, for instance, it would be better to drop the terms Lower, Middle, and Upper Lias, and speak merely of Lias Clays, Sandstones, and Ironstones, leaving it to the palæontologist to decide to which of the three sub-divisions the strata distinguished on the map ought in each locality to be assigned. It should be added, however, that Mr. Judd has something to say even from a palæontological point of view for the classification of the Geological Survey;[1] though it must be confessed that his words sound somewhat as if he were dutifully trying to make the best case for a line which his official position rather than his own convictions led him to adopt.

For the painstaking zeal with which the authors have in succeeding chapters worked out the palæontology of the different minor sub-divisions, and described the localities where each may be studied, and for their long and elaborate descriptions and figures of the fossils the thanks of all geologists, and specially of those interested in the district, will be gratefully rendered; and as they have thought it necessary to defend the minute and detailed character of their work, a word may be added on this head. It is somewhat unfortunate that a special term, "zones," has been applied to those lesser sub-divisions, which in common with the majority of palæontologists they have sought to establish. It leads to the notion that a "zone" is something different from a "formation," and to a vague fear that the zone-maker is introducing some new and presumably unsafe method into geological classification. But if, as the evidence seems to show, each zone is characterised not indeed by fossils entirely peculiar to itself, but by certain assemblages of fossils which are not met with in any other zone, then the principle on which zones are established is identically the same with that which determines the larger sub-divisions, and the only difference between a zone and a formation is that the one requires more care and labour to detect and define it than the other. As our authors remark, we are quite in the dark as to the causes that brought about the change from the fauna of one zone to that of the succeeding zone; but just the same remark applies in many cases to the more marked differences between the fauna of successive formations. If, then, the palæontological facts on which zones are based can be securely established, the existence of these minor sub-divisions is a fact which geologists cannot refuse to recognise; but it is just here that the rub occurs. The intolerable complexity and uncertainty of palæontological nomenclature, the utter want of agreement on points of the first importance between many leading palæontologists, the strong tendency which so often exists to a multiplication of species in order to justify existing sub-divisions or even to increase their number, have raised suspicions and distrust in palæontological grouping, unfounded perhaps, but for which palæontologists have only themselves to thank. What can, for instance, be more monstrous than the idea that the time at which it lived ought to be taken into account in the definition of a species? An idea which, according to one of our authors, only a limited number of palæontologists are prepared to repudiate. If you have two creatures exactly alike in every respect, what reason can there be for calling them by different names because one is alive now and the other died ages ago? The idea is closely akin to the old superstition that the volcanic rocks of the earlier periods must have been different from those of the present day, and that if no real difference can be detected between them, they at least ought to be called by different names. Such a notion is now scouted by the most advanced petrologists, and when palæontologists follow in their steps, they may be assured that the objections which some geologists have urged against their smaller and less easily recognised sub-divisions will no longer be heard.

We cannot help thinking that the authors have laid rather too much stress on the littoral character of the Lias in the northern part of the North Riding. They lean to the conclusion that the Lias never extended much further towards the north-west than the points where we now last see it in that direction; in fact one or two of their expressions seem to hint that the Lias of the North Riding was deposited in a basin of its own. This can hardly be admitted; the persistence over large areas of the different palæontological zones of this formation shows that the Liassic sea formed one great life province, and that however it may have been broken up by projecting headlands or insular masses of land, there was free communication between all its parts. That the water was shallower in some places than others is likely enough, and variations in depth would seem to be sufficient to account for the changes which occur in the lithological character of the Lias in North Yorkshire without invoking the neighbourhood of an extensive shore line. A very interesting fact is the decided unconformity between the Lias and the Inferior Oolite east of Easingwold; the upheaval to which it is due was only the forerunner of the still more important movements which a little later on drove back the sea and established estuarine and terrestrial conditions over a large part of the North Riding.

---

[1] "The Geology of Rutland" (Memoirs of the Geological Survey), p. 45.

It is not necessary that a scientific work should be a model in point of style, but it is a matter for regret when scientific writers neglect the graces of composition, and it is certainly a blot on the work before us that the writing is occasionally obscure, and that instances of somewhat slipshod English are not uncommon in it.

If we stop here it is not for want of more to say; a book as rich in matter as this would furnish texts for many another lengthy disquisition. We may fairly congratulate the authors on having produced a monograph which will take a high place among standard works on local geology, and may be recommended as a model for writings of a similar kind. We wish every natural geological district in our island was likely to be worked out with the same amount of patient labour and faithful description as Messrs. Tate and Blake have bestowed on the Yorkshire Lias. A. H. G.

OUR BOOK SHELF

Die Fauna der Clavulina Szabói Schichten. Von Max. von Hantken. I. Theil: Foraminiferen. Mit 16 Tafeln. (Buda-Pesth, 1875.)

EVERY visitor to the Loan Exhibition of Scientific Apparatus at South Kensington must have noticed in the Geological Department some beautiful series of preparations of Foraminifera and Bryozoa from Hungary. These have been sent by Dr. von Hantken, the Director of the Hungarian Geological Survey, who has greatly distinguished himself by the remarkable skill with which he has studied these minute fossil organisms. One of these series of fossils, which English geologists have now such a valuable opportunity of studying, illustrates the remarkably rich Foraminiferal fauna of the zone of Clavulina Szabói in Eastern Europe, a fauna which is very admirably described in the work before us. This memoir is a reprint of a portion of the fourth volume of the "Mittheilungen aus dem Jahrbuche der kön. ungar. geologischen Anstalt," which is published in both the Hungarian and German languages.

The Clavulina Szabói Schichten are a series of clays, marls, and marly limestones, sometimes glauconitic, which are situated at the junction of the Eocene and Oligocene formations, and appear to have a wide distribution in Western Hungary. These strata are very remarkable for the wonderful richness of their fauna, especially in Foraminifera, Bryozoa, Echinoderms, and Mollusca, while in certain portions of the formation great numbers of fish-remains have also been found. No less than 213 species of Foraminifera have been described by Dr. von Hautken as occurring in these beds, and their distribution in the Eocene and Neogene strata of Eastern Europe, as well as in the strata which most nearly correspond in geological age with the zone of Clavulina Szabói in Germany and Italy respectively, are shown by the author in a very useful table. The lithographic plates with which this monograph is illustrated are beautifully executed, and reflect the highest credit on the present condition of the art of book-illustration in Hungary. Although the dimensions of each of the forms described is given with great exactness in the definition of the species, we think it is unfortunate that the extent to which each figure is magnified is not also indicated either on the plates themselves or in the descriptions which accompany them.

J. W. J.

Elements of Algebra for Middle-Class Schools and Training Colleges. By Edward Atkins, B.Sc. (Collins's School Series, 1876.)

THIS is a handy book, covering the ground usually occupied by similar treatises on the subject. It is a fairly independent work, keeping near the beaten track as regards results arrived at, but giving these results in many cases by new modes of proof. The chief additional features of interest are in some articles on "Imaginary Quantities," "Properties of Numbers," and "Determinants." We do not like the use of the expression, "It is easily found," and so on, in a few passages, and we must point out that there are a great many mistakes, not merely typographical ones. These are faults which can easily be rectified in a second edition. Care also should be taken to correct the numerous wrong references.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*]

Carl Jelinek

ALLOW me to correct a little inadvertency in the necrology of Carl Jelinek (NATURE, vol. xv. p. 85). In line 8 from commencement "Prague" should be read instead of "Vienna," as the former and not the latter observatory was then under the direction of Kreil. Jelinek passed four years (1843-1847) as assistant in the Vienna observatory, then under my direction, and published in that period a valuable memoir on hygrometrical observations made at Vienna in the years 1829-1845, besides several astronomical observations and computations in the *Astronomische Nachrichten*, and in the *Annals* of the Vienna observatory. CH. DE LITTROW

Vienna, November 29

Ancient Solar Eclipses

IN NATURE, vol. xv. p. 65, is given the result of calculation of the solar eclipse of June 14, B.C. 763.

As soon as notice of the probability of this eclipse was given by Sir Henry Rawlinson (in May 1867), I asked the assistance of Mr. Hind for its computation. Mr. Hind most kindly acceded at once to my request, and sent to me on June 19, 1867, the following results, which he permits me now to offer to NATURE. They were transmitted to Sir Henry Rawlinson on June 20, 1867, and to Mr. George Smith on October 17, 1867.

SOLAR ECLIPSE, – 762, JUNE 14-15.

Path of Totality, according to the Lunar Tables of Hansen and the Solar Tables of Le Verrier.

Greenwich Mean Solar Time, B.C. 763.	Northern Limit.		Central Line.		Southern Limit.	
	Long.	Lat.	Loug.	Lat.	Long.	Lat.
h. m.	° ′	° ′	° ′	° ′	° ′	° ′
June 14, 18 54	35 23	37 52	36 3	37 7	36 44	36 20
19 0	38 29	38 53	39 6	38 4	39 43	37 14
19 6	41 33	39 46	42 7	38 54	42 39	38 3
19 12	44 35	40 31	45 4	39 38	45 32	38 46
19 18	47 34	41 9	47 59	40 14	48 23	39 21
19 24	50 32	41 40	50 52	40 45	51 12	39 49

The path of the shadow defined by these numbers differs sensibly from that given in Nature, vol. xv. p. 65. It passes to the north of Nimrud instead of the south.

With the permission of Mr. Hind, I also transmit the following list of solar eclipses, computed by him, of which the results are preserved in the manuscripts of the Royal Observatory :—

Negretti's Reversible Thermometer and the Arctic Expedition

Capt. Nares presents his compliments to the editor of Nature, and requests him to correct a mistake which Capt. Nares inadvertently made in his official report to the Admiralty concerning the late Arctic expedition, and which has been reprinted in Nature.

In obtaining some deep-sea temperatures, which proved the existence of a sub-stratum of water warmer than that at the surface, the instruments used were the reversible thermometers of Negretti and Zambra, not Casella's. The Casella thermometer was used on other occasions, but not at the time referred to.

H.M.S. *Alert*, Portsmouth, November 30

The Arctic Expedition

Two or three considerations have led me to believe that possibly the recent Arctic Expedition has not been so fortunate as might have been wished, and that the same amount of foresight, courage, and energy, expended on a similar expedition another year might be attended with much more satisfactory results.

The considerations referred to are these :—

Fifty years ago Sir Edward Parry traversed a distance of some hundreds of miles in sledges upon what he at first supposed to be the main pack ; but on finding that as fast as he travelled northwards he was drifting to the south, he concluded what he had mistaken for the main pack, was after all only a loose floe of immense extent.

Now in 1872, on the return of the American expedition, we were all given to understand that an open Polar Sea existed where instead is now found a sea of ancient ice. All testimony concurred in pointing to this open sea. The climate was warmer than further south ; birds were seen flying north ; a creeping herbage flourished, and bright flowers were not absent. Musk oxen, rabbits, and lemmings also abounded. Now these *Polaris* explorers were neither mendacious nor stupid ; and it seems to me that it is rather premature to set down their inference from all they observed as a mistake.

Now, sir, my theory, true or false, new or old, is this :—This Palæocrystic Sea is really a vast floating island of ice ; say 500 miles in diameter. Just like the ice in a pail or on a pond, it melts in the hot weather at the edges, and then, disengaged from the land, it floats hither or thither, according to the direction of the prevalent winds or currents. If this theory be correct, it accounts for Parry's disappointing journey, for the inferences based on the *Polaris* observations, and for the otherwise unaccountable fact that the ice encountered by the recent explorers is undoubtedly ancient. The fact that the vast floe showed no signs of drifting away last summer only shows that the wind was unfavourable, or that this northernmost Greenland coast, when once the ice is stranded, does not easily relinquish its grasp. Possibly if a *Hecla* had attempted in 1876 what was impracticable in 1827, or if an *Alert* had tried in 1827 what has just proved a failure, both enterprises would have succeeded.

Next time two opposite routes must be undertaken simultaneously, of which one will fail and the other succeed.

Wordsworth Donnisthorpe

The Age of the Rocks of Charnwood Forest

In reference to the letters which have appeared in Nature (vol. xv. p. 97) allow me to say, in the first place, that I neither attached, nor intended to attach, any discredit to Mr. Woodward's very useful manual for the statements it contains in reference to the age of the Charnwood Forest Rocks. On the other hand, I am gratified to find that so competent an observer as the Rev. T. G. Bonney concurs with me in the view "that there is not a particle of evidence for their Laurentian age." This was the special point of my letter; and I fail to see that Prof. Green's hypothetical inferences from certain sections at Markfield (of which he fears that he has kept no record) are of much value in the question. Prof. Green, however, admits that the great mass of these rocks give no evidence of Laurentian age.

As regards what may be the respective limits of "Cambrian" and "Silurian" rocks that is another question. I am quite aware that Sedgwick claimed formations as "Cambrian" which are not so recognised by the Geological Survey, nor by the majority of authors, continental as well as British ; for example, M. Barrande. To which of the series of formations belonging to the Cambrian system of Sedgwick the forest rocks are to be referred I am not prepared to say; but I think it must be allowed that the negative evidence founded on the absence of fossils ought to have some weight in favour of the view that they are referable to the horizon of the "Cambrians" of the Geological Survey rather than to that of the Llandeilo or Caradoc beds.

Mr. Bonney's comparison of the forest rocks with those of the volcanic series of the Lake District is very suggestive ; nor is the correspondence of the strike of the beds in both districts without its weight, where every circumstance ought to be taken into consideration in question of such uncertainty. It would also be very desirable if some general understanding could be arrived at regarding the respective limits of the Cambrian and Silurian systems. There are scarcely two authors who adopt the same view on this subject. Theoretically it may be a matter of small consequence ; but practically it gives rise to confusion amongst geologists and amongst students of geology. As this is the age of "conferences" why should not a conference of Palæozoic geologists meet and lay down a frontier line for the two kingdoms, which would last, perhaps, for a generation, and until the "instinct of nationality" crops up and brings on another conflict between the inhabitants of Cambria and Siluria, and their allies respectively?

Edward Hull

Geological Survey Office, Dublin, December 4

"Towering" of Grouse, Partridges, &c.

Most of your readers doubtless know what is meant by the towering of game-birds ; but, for the sake of those who do not, I will begin by describing the facts. When a partridge, for instance, is hit while on the wing by a few pellets of shot—perhaps only by one or two—the flight may continue for a variable distance ; but, if the bird is a "towerer," a slight irregularity soon begins to show itself, after which the flight rapidly becomes more and more laboured, till eventually the bird ceases its onward motion altogether. The direction of the flight now changes from the horizontal to the perpendicular, and with a rapid fluttering sort of action the bird rises to a variable height, when all motion suddenly ceases, the animal falls like a stone, and the sportsman then knows that when he finds his partridge it will be lying dead on the exact spot where he "marked it down."

Before proceeding to state the cause of these curious movements, I should like to draw more prominent attention to the facts, first, that the time after receiving the wound during which horizontal flight continues is variable ; second, that the limits of variation are tolerably definite, a bird never towering until it has flown some distance after being shot, and never flying any very great distance before towering ; and third, that the height to which the bird rises is also variable, this height being sometimes only 1 or 2 feet, and at other times 40 or 50.

Now I suppose there is not a sportsman in the country who has not witnessed these phenomena scores and scores of times, and I dare say there is scarcely one of that numerous body who, if asked to assign the cause of these phenomena, would hesitate for a moment in his reply. From the time he first saw a bird tower, he has probably satisfied himself that the current hypothesis is the only one that can explain the curious facts; and if his interrogator should venture to doubt that cerebral injury is this cause, he would probably point to a drop of blood in the beak as a final answer to such scepticism. This drop of blood has doubtless always seemed to him such a complete verification of the current hypothesis, that he has probably never waited to ask himself the following questions:—1. Why is towering so common? The head of a partridge or grouse is a small object, and therefore not likely to be often hit. Moreover, common sense may show that if towering is due to cerebral injury, such injury must be of a very local and definite character as regards the brain: some particular part of that organ must be injured to the exclusion of all other parts, or else the effect would be instant death. This consideration would lead us to expect that towering, if it is due to cerebral injury, should be of exceedingly rare occurrence. 2. Why does a bird always fly some considerable distance before towering? If the action is due to cerebral injury, we should expect the former to ensue immediately upon the infliction of the latter. 3. Why is the distance which a bird flies before towering so variable? 4. Why is the height to which it does tower so variable? 5. Why is it that birds tower most frequently when shot from behind? 6. Why is it that we never see the hole in the skull through which the pellet has passed?

In view of these difficulties besetting the ordinary hypothesis, and in the hope of ascertaining the exact seat of cerebral injury if this hypothesis were the true one, I have last year and this year dissected a number of partridges which I had observed to tower, and in every case I found the cause of death to be the same, viz., pulmonary hæmorrhage. In all my specimens the lungs were gorged with extravasated blood. It thus becomes impossible to doubt that we have here the true cause of towering; and, as is always the case with true causes, examination will show that it is sufficient to explain all the effects. Towering is common, because the lungs expose a large area to receive the shot, and an area which is especially liable to be crossed by a single pellet from a bad marksman when, as is most usual, the bird is shot from behind. The bird always flies a considerable distance after being hit, because it takes time for the blood to pour into the spongy texture of the lungs from the open ends of the severed blood-vessels. The distance flown is variable, because it depends on the size and number of the severed blood-vessels—*i.e.*, the rapidity of the bleeding—which of course is also variable. The height to which the bird towers is variable, because depending on the same cause. The drop of blood in the beak comes from the bleeding lungs through the wind-pipe—the latter organ in most of my dissections having been found full of clotted blood. Lastly, we do not find any indications, either externally or internally, of cerebral injury, for the simple reason that no such injury has taken place.

Any one who is not a physiologist may here ask, Why does pulmonary hæmorrhage give rise to such very peculiar movements as those that occur in towering? The answer must certainly be, that in these towering movements—which, be it remembered, only take place immediately before death—we have to do with the characteristically convulsive movements which in all animals mark the last stages of asphyxia. That in birds these movements should show themselves mainly in the wings, might, I think, be reasonably expected, seeing that the pectorals are the principal muscles in the body—and all sportsmen are aware how the particular birds in question exhibit violent fluttering motions of their wings when dying from any violent cause, just as rabbits, under similar circumstances, exhibit violent galloping motions of their principal muscle-masses in the hind legs. But why the convulsive movements of asphyxia should show themselves in these birds in the form of upward flight, is a question which I cannot answer. It seems, however, to be a question of some interest to the physiologist, and if worked out might possibly tend to elucidate that obscure subject, the mechanism of flight. Of course to investigate the phenomena of towering, asphyxia of birds would require to be produced in the laboratory; and here I must leave the matter in other hands, for although I have a licence to suffocate as many birds as I can in the pursuit of sport, I have no licence to suffocate a single bird in the pursuit of science.

And, in conclusion, may I suggest that those sportsmen who annually conduct their experiments on asphyxia by the thousand, should endeavour to glean from them one result of some little value to science? It would be of interest to know what birds tower and what birds do not. So far as my own observation extends, the peculiarity in question seems to be confined to members of the grouse genus, nearly all the endemic species of which I have observed to tower. But, excepting those species, I have never known any other bird to do so. By publishing this notice in your columns, therefore, I hope to obtain information from any of your readers who may have observed the well-known phenomena in birds of other genera. GEORGE J. ROMANES

Squirrels

ON the lawn before the window near which I am writing is erected a tripod of three lofty poles, at the summit of which is suspended a basket containing nuts and walnuts. The squirrels, of which there are many in the shrubberies and adjoining plantations, ascend these poles, extract a nut from the basket, and quickly make their way down and across the lawn, in various parts of which they bury their nuts, scratching a hole in the green turf, putting in a nut, filling up the hole, and, lastly, with much energy, patting the loose materials with their feet till the filling-up is made firm and solid. This morning for a considerable time only one squirrel was at work, giving me a better opportunity of observing the mode of operation. His journeys were made in all directions, and varied from 5 feet to nearly 100 yards, never, so far as I could observe, going twice to the same place or even nearly so. The squirrels, I am told, forget the spots where they hide the nuts, and in the following spring the lawn, which is very spacious, is dotted with the young plants of nuts and walnuts. As the colours of flowers attracting bees and moths promote fertilisation, so the racy flavour of a nut, irresistible to a squirrel, contributes to the distribution of its kind.

Turvey Abbey, November HENRY H. HIGGINS

Mr. Harris's Challenge to Mathematicians

IN an advertisement in NATURE (vol. xv., p. xxxviii.) Mr. Harris (Kuklos) challenges mathematicians "to examine and disprove if they can" his published demonstration of the value of π. Presumably he reads this publication; if so, we would direct his attention to an article on "Cyclometers and some other Paradoxers" in vol. xii., p. 560, vol. xiii., p. 28. The part which is concerned with his approximation will be found on p. 29. Reasoning, however, which we venture to think will satisfy mathematicians, may not, we fear, convince Mr. Harris.

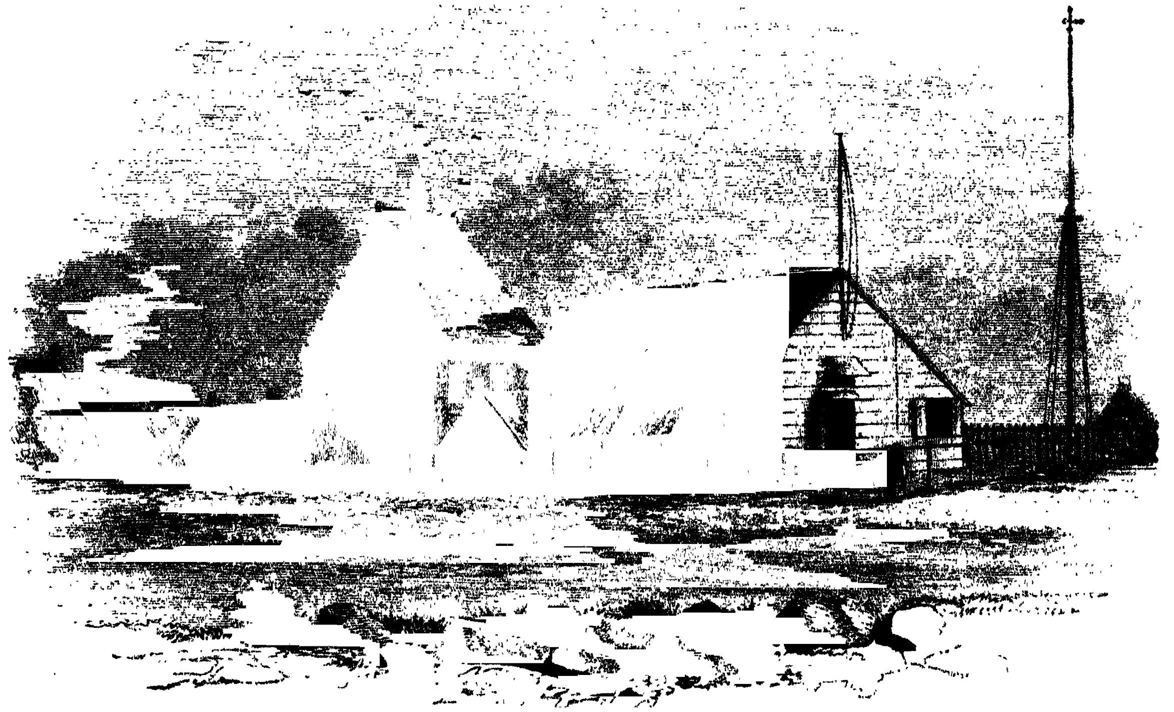
A ZOOLOGICAL STATION ON THE NORTH SEA

REFERENCE was made in NATURE (vol. xiv. p. 535) to the resolutions passed at the recent meeting of the Association of German Naturalists and Physicians at Hamburg, as to the establishment of zoologico-botanical stations on the German coast. The distinguished names of those appointed to draw up a memorandum, which is to be presented to the Imperial Chancellor, the Bundesrath, and the Governments of the several States of the Empire, will no doubt be of the greatest service in securing success to a scheme so universally approved of by all students of biology.

The following is a brief sketch of similar endeavours made in Holland a year ago and of the results arrrived at during the summer of 1876:—The Netherlands Zoological Association, at a meeting held in November, 1875, recognised the necessity of founding an establishment on the Dutch coast, where anatomical and microscopical investigations of the fauna and flora of the North Sea might be carried on at leisure, and which could at the same time be made serviceable for physical, chemical, and meteorological observations on this part of the German Ocean. A committee, consisting of Prof. Hoffmann, Drs. Hoek and Hubrecht was appointed to take the necessary steps towards the realisation of this scheme, and to provide temporary accommodation during the summer months of 1876, where members of the Association might engage in these pursuits. In February, 1876, the Committee was obliged to report that no suitable accommodation was to be found in those localities on the Dutch coast, where the erection of a zoological station might prove a success, and that the funds of the Association would not suffice to carry out the scheme on the scale to which an institution like this ought to aim at from the beginning. The committee proposed to raise the necessary funds by a public subscription as well as by the issue of shares of 10 guilders each, paying no interest, but terminating within a fixed number of years. The Association might thus obtain a building of its own, which, if it were made of wood, might be transportable from one locality on the coast to another according to season and varying abundance of the material for study. This proposal was agreed to, and within a few weeks about 400*l.* were raised, a sum more than sufficient to commence with.

Accordingly a wooden shed similar to those which had served the Dutch astronomical party for the observation of the transit of Venus in Réunion was constructed. It has four windows on each side with corresponding working tables and a small room adjoining, where the vessels containing marine animals may be kept in darkness, and where an apparatus for oxygenising the sea-water is to be kept in constant working order. This embryo zoological station, more resembling a block-house in the back woods than Dohrn's well-known institution, is, however, fitted out with all the requisites for histological and microscopical research prescribed by the different methods of investigation of the present day. Next to the numerous chemical desiderata a store of glass and crockeryware is kept in readiness, a stock of standard works and other books which may in any way prove useful is selected from the library of the Association; in short, everything provided for, microscopes and steel instruments only excepted. A set of dredges, towing nets, cross-bars with hempen swabs for scraping the bottom (Marion, Lacaze Duthiers), pelagic nets, &c., complete the inventory, and have to serve for the daily renewal of those marine forms which would be the objects of investigation in the station itself.



ical Station, 1876.

In the first week of July all this was transported to Helder, the northern seaport opposite to the Island of Texel, and erected on the top of the great dyke which there protects the Low Countries behind from inroads of the sea. Regular dredging parties were organised, the work being carried on partly in sailing vessels hired for the occasion, partly by means of a small steamer belonging to the Navy, which the Minister of the Marine placed at the disposal of the Zoological Association. The work was carried on for eight weeks; towards the end of August, when continual bad weather set in, the station was closed, taken down, and transported back to Leyden, in order to be erected again on another point of the coast next summer.

During those two months ten members of the Association availed themselves of the opportunity of studying the marine fauna of that part of the Dutch coast, and in many branches interesting results have been arrived at which will in time be published in the Annual Reports of the Association. The shifting sands, which everywhere form the bottom round the coasts of Holland as well as the total absence of rocks and cliffs may explain the deficiency of many sessile forms which form so conspicuous a part of the fauna of the French and British coasts. Crustaceans and Annelids were numerically, perhaps, the best represented; next came the

s, the Polyzoa, and different

s of Molluscs and Echinoderms.

et with, neither were Holothurians.

they were represented by the composite Botryllidæ, which could be had in immense numbers in some of the shallower parts at the entrance of the Zuyder Zee, mostly attached to blades of the Zostera. The stones employed in the construction of the great dyke, which are partly lying loose, were of importance, as they usually covered over the haunts of numerous Crustaceans, Nemerteans, &c. A no less rich harvest was got from the driftwood now and then met with, and from the wooden palings serving in the construction of the wharfs, &c., in the harbour, which were submerged at high tide.

Altogether this first summer of the Dutch Zoological Station gave ample proof of its practicability. It would perhaps be a good idea to act conjointly in future with the German men of science, and to add a third permanent station to those proposed in the German Committee's Report (Kiel and Heligoland), say at Flushing. If, then, one other station were to be erected on the English or Scotch coast (St. Andrew's Bay ?), a conjoint attack could be made on the mysteries still hidden in that part of the ocean which is inclosed by our neighbouring coasts. The healthy competition which would arise out of this division of the work to be done, can only be favourable to the common end—an accurate knowledge of the natural history of our own seas, and a constant opportunity of studying their animal and vegetable productions in the fresh state.

SENSITIVE FLAME APPARATUS FOR ORDINARY GAS PRESSURE, AND SOME OBSERVATIONS THEREON

A GLASS or metallic tube, about 5 inches long, and $\frac{5}{8}$ in diameter, is closed at one end with a perforated cork, through this cork slides a piece of $\frac{1}{8}$ inch tubing, about 6 inches long. One end of this is either drawn out to a jet, or closed in the blow-pipe flame to reduce its diameter to about $\frac{1}{16}$ inch, and the other end is connected to a gas supply. (Fig. 1.)

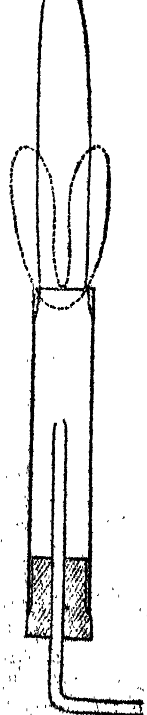


FIG. 1.

The outer tube is held in a suitable support, and the inner tube is pushed through the cork till it nearly reaches the mouth of the outer one, and a light then applied. It now gives a long steady flame.

Experiment I.—Lower the inner tube till the flame is on the point of roaring. It will now be found very sensitive to noise. Snapping the fingers at a distance of eight or ten yards will cause it to contract fully $\frac{4}{5}$ of its height. The most suitable flame for this is about 6 inches high.

Experiment II.—Adjust the gas to give a flame of about $4\frac{1}{2}$ inches high, and gradually raise the inner tube. A point will be reached at which the flame becomes sensitive, not to noise, but note; and it will be found to respond to a certain note by dividing into two portions, and while this note is produced it will continue divided. It is difficult to keep the exact note by whistling with the mouth, and therefore a glass whistle with paper slider should be used, or, better still, a singing tube with adjustment.

Experiment III.—Arrange two singing tubes to give the responding note. The flame divides. Now make one tube a little sharper than the other, so as to beat slowly. The alæ of the flame alternately recede and coalesce.

Experiment IV.—Using the whistle; blow it so hard as to produce higher octaves of the responding note. The flame will be unaffected, as though in perfect silence.

The dimensions of the instrument are open to great variation, and also the size of the flame. For lecture work, a flame $1\frac{1}{2}$ or 2 feet would be more suitable, though less sensitive, and neither dividing nor shortening so perfectly as the sizes given above. It will act effectively with any pressure of gas, from $\frac{1}{10}$ inch (of water) upwards, and the sliding jet makes it equally sensitive with a large or small gas supply.

Observations on the Escape of Gas from Contracted Openings, and on a Differential Pressure Indicator.

Glass tubes of about $\frac{1}{4}$ in. bore are joined as shown in Fig. 2. At D the tube is slightly bent so as to retain a little drop of water. The gas enters at C, and then divides into two channels, one towards B, the other towards A.

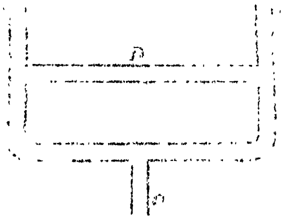

FIG. 2.

If one of the exits be contracted, say B, then the water moves towards A. Certain precautions have to be observed, the conditional arrangements of which need not be mentioned here.

Experiment I.—Connect to each, A and B, a tapering jet, and C with the gas supply. Get the water stationary. Now light, say, B, the water will move towards A, showing that the exit of the gas is retarded by being ignited.

This is rather a remarkable result, seeing that the gas is hotter, and therefore more mobile, and also that the heat must enlarge the aperture. Now light A, and the water will return to zero.

Experiment II.—Connect B with a sensitive flame apparatus, A remaining as before, light and adjust to zero. Now sound the responding note and the water moves towards A, showing that the outflow of gas is retarded by a certain note. Now adjust the sensitive flame for noise, and rapidly snap the fingers or stamp the foot, and the water will still move towards A.

Experiment III.—Arrange as in II., then extinguish the sensitive flame and readjust to zero. Produce the responding note, and the same movement of the water will be observed. This shows that an issuing jet is affected in the same manner by a sound, whether ignited or otherwise.

Experiment IV.—Fix the sensitive flame apparatus adjusted for note under a large jar open at both ends. A large stoppered gas jar answers very well. Fix three balls of spongy platinum, *a*, *b*, and *c*, upon a piece of thin platinum wire so that the point of the quiescent flame just reaches *b*, and the points of the responding flame reach *a* and *c* respectively. Now extinguish the flame without turning off the gas. The issuing gas will cause the ignition of *b*. Now sound the responding note, and *b* will cool, and *a* and *c* will be ignited. This confirms the previous observations, and forms a rather pretty lecture experiment. The object of the gas jar is merely to protect from air currents.

R. H. RIDOUT

ON THE CONDITIONS OF THE ANTARCTIC[1]

II.

ALTHOUGH no land *débris* of any kind was observed by us on the icebergs, there cannot be the slightest doubt that such is carried by them all over the region and distributed on the bottom. The samples brought up by the sounding instrument consist almost entirely of comminuted clays and sands, and the dredge always contained in considerable quantity, about the meridian of 80° E., chiefly basaltic pebbles, and, further to the eastward, pebbles and larger fragments of metamorphic rocks, granite, gneiss, mica-slate, hornblende-slate, clay-slate, and chlorite-slate.

While the evidence may be said to be conclusive that these icebergs have their origin on land, it seems to me that the presumption is greatly in favour of the land at their breeding-place having been comparatively low and flat, and bordered for a considerable distance by shoal water. Although the white ice which forms the exposed portion of the flat-topped southern icebergs is very hard, its specific weight is considerably below that of absolutely compact ice. Allowing for this difference, and supposing that one-seventh part of the ice is raised above the water, supposing also that the berg is symmetrical in form, which, from its appearance and probable mode of origin is likely to be the case; before it has been subjected to the action of the sea, the submerged portion would be 1,200 feet in depth, the berg would float in water 200 fathoms deep, and the average thickness of the land ice-cap would be 1,400 feet. From the comparatively small number of icebergs at the point where we crossed the Antarctic circle, and so far as we could judge from our own observations and the previous observations of others, for a considerable distance to the west of the meridian of 80° E., we were led to believe that the place of their formation, the land and the belt of shallow water girding it, was at a very considerable distance from us.

Although in the present state of our knowledge it would be rash to form any very definite opinion as to the conditions of the region included within the parallel of 70° S., still there are some indications which have a certain weight. We have no evidence that this space which includes an area of about 4,500,000 square miles, nearly double that of Australia, is continuous land. The presumption would seem rather to be that it is, at all events, greatly broken up, a large portion of it probably consisting of groups of low islands united and combined by an extension of the ice-sheet. One thing we know, that the precipitation throughout the area is very great, and that it is always in the form of snow, the thermometer never rising, even in the height of summer, above the zero of the centigrade ——.

Various patches of Antarctic land are now known with certainty, most of them between the parallels of 65° and 70° S.; most of these are comparatively low, their height, including the thickness of their ice-covering, rarely exceeding 2,000 to 3,000 feet. The exceptions to this rule are Ross's magnificent volcanic chain, stretching from Balleny Island to a latitude of 78° S., and rising to a height of 15,000 feet; and a group of land between 55° and 95° west longitude, including Peter the Great Island and Alexander Land, discovered by Bellingshausen in 1821; Graham Land and Adelaide Island, by Biscoe, in 1832; and Louis Philippe Land, by D'Urville, in 1838.

The remaining Antarctic land, including Adelie Land, discovered independently by Dumont D'Urville, and Lieut. Wilkes, in 1840, in long. 140° 2' 30", lat. 66° 45' S; Clairie Land, discovered by the same navigators about 3° farther to the westward; Sabrina Land, discovered by Balleny, in 1839; and Kemp Land and Enderby Land, discovered by Biscoe, in 1833, nowhere rise to any great height. If we were justified in adding the "strong appearances of land" reported by Lieut. Wilkes, which would virtually connect Ringgold's Knoll not far from the Balleny Islands, with a point in long. 106° 18' 42" E., lat. 65° 59' 40" S., by a continuous coast-line of moderate height, the extent of land of this character would be considerably increased.

The geological structure of the Antarctic Land is almost unknown. South Victoria is actively volcanic and consists doubtless of the ordinary volcanic products. D'Urville's party landed on Adelie Land and found rocks of gneiss. Wilkes reports having landed on an iceberg, long. 106° 18' 42", and finding "imbedded in it in places boulders, stones, gravel, sand, and mud or clay. The larger specimens were of red sandstone and basalt." At the same place Lieut. Ringgold found that "the icebergs near at the time presented signs of having been detached from land, being discoloured by sand and mud." From one iceberg he procured several pieces of granite and of red clay which had been frozen in. Beyond these observations, and our own on the nature of the pebbles brought up by the dredge, we have no information.

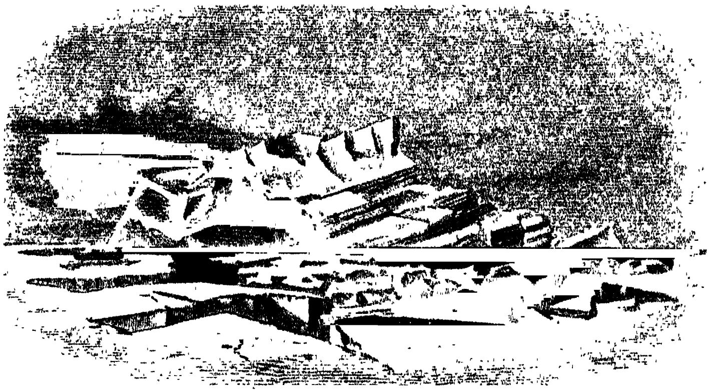

FIG. 3.—February 25, 1874. Lat. 63° 49' S., Long. 94° 51' E.

That the area within the parallel of 70° S. is continuously solid, that is to say, that it is either continuous land or dismembered land fused into the continental form by a continuous ice-sheet, I think there can be little doubt. The local cases of abnormal distribution of temperature which produce such remarkable conditions of climate even within the North Polar Sea exist in the southern hemisphere only to a very slight degree; and we know by the absence of any well-defined local Antarctic return-currents comparable with the Labrador current, or the current round the south of Spitzbergen, that the function of such currents as the Gulf Stream in ameliorating the northern climate, and breaking up the ice, and producing a circulation even in the highest northern latitudes, is not in any way represented in the south.

In favour of the view that the area in question is broken up, and not continuous land, two considerations appear to me to be very suggestive. If we look at an ice-chart we find that the sea is comparatively free from icebergs, and that the deepest notches occur in the "Antarctic continent" at three points, each a little to the eastward of south of the great land-masses, and I have little doubt that the explanation of this fact lately suggested by Dr. Neumayer is the correct one. The great equatorial current impinging upon the eastern coasts of the continents bifurcates upon each, and both branches acquiring a slight but decided easterly set by their excess of initial velocity, pass northwards and southwards directed for a time by the land coasts. But the fate of the southern is very different from that of the northern branches. Instead of accumulating and "banking down" in the confined gulfs, the Atlantic, the Pacific, and the Indian Oceans, they at once pass into the waste of the "water hemisphere," and are almost merged in the great drift current which sweeps round the world occupying a belt from 600 to 1,000 miles broad in the southern sea. But while the greater portions of the Brazilian current, the East Australian current, and the southern branch of the Agulhas current are thus merged they are not entirely lost; for at their points of junction with the drift current of the westerlies the whole belt of warm water is slightly deflected to the southward, and it is opposite these points of junction that we have the comparatively open sea and the penetrable notches in the southern pack.

---

[1] The substance of a lecture by Sir C. Wyville Thomson, F.R.S., delivered the City Hall, Glasgow, on November 23, under the arrangements of the asgow Science Lecture Association.] Continued from p. 106.

Thus Ross, in 1841 and 1842, after forcing his way through the moving pack, which he found sufficiently open to allow of his doing so, passed between the meridians of 170° E., and 170° W., to the latitude of 78° 11′ S. Weddell in 1823, and Ross in 1843, reached the parallels of 74° 14′ and 71° 30′ S. respectively, between the meridians of 15° and 30° W. The case of the Brazilian current is, however, a little more complicated than that of the others, for there is high and extensive land between the meridians of 55° and 65° W., in 65° south latitude, and the warm current already led far to the southward by the south-American coast appears to bifurcate upon Graham Land, and to produce another bight, in 90° west longitude, a little to the west of the southern point of the South American Continent. In this bight, Cook, in 1771, and Bellingshausen in 1821, pushed nearly to the 70th parallel of south latitude.

The opening caused by the deflection of the southern branch of the Agulhas current towards Kerguelen and the Heard Islands, has not yet been fully explored, but what has been already done in that direction seems to be in striking confirmation of this view. We had indeed arrived independently at the same conclusion before reading Dr. Neumayer's paper. At the point where we crossed the Antarctic Circle (Long. 78° 0′ E.), and for some distance to the westward there were few icebergs, and the sea was almost clear to the south-west. It was Capt. Nares' opinion that had it been considered desirable and had the attempt been made earlier in the season, it would have been easy for us to have pushed southwards in that direction—how far we had no means of ascertaining—but the pack was moving about round us, and for the reasons already given we believed the barrier to be at a considerable distance.

But we not only observed the effect of the influx of warmer water; we were able to detect its presence by the thermometer. Referring to the results of a serial temperature-sounding of February 14, with a surface-temperature of − 1°·2 C., between 300 and 400 fathoms there is a band rising to more than half a degree above the freezing-point. That this warm layer is coming from the north there is ample proof. We traced its continuity with a band at the same depth gradually increasing in warmth, to the northward; and it is clear that its heat can be derived from no other source, and that it must be continually receiving new supplies, for it is overlaid by a band of colder water tending to mix with it by convection.

It is of course possible that the three warm currents may, by coincidence, be directed towards three notches already existing in a continental mass of land; but such a coincidence would be remarkable, and there is certainly a suggestion of the alternative, that the "continent" may consist to so great an extent of ice as to be liable to have its outline affected by warm currents.

The second consideration is that during summer, the only time when these regions have been as yet visited, the greater part of the outline of the area representing the Antarctic continent has been found to consist of moving ice-pack. The prevailing winds within the Antarctic Circle are from the south-east, and as a rule the pack and the icebergs are moving to the westward, and fanning out from a centre. Almost all the navigators who have passed the belt of pack have received the impression that there was open water within, that, in fact, by that time, late in the summer, the pack of the year had been drifted a considerable distance from its nucleus—the land or the continuous ice-sheet. If this be so it would at all events indicate that the "Antarctic continent" does not extend nearly so far from the Pole as it has been supposed to do.

I conceive then that the upper part of one of these tabular icebergs, including by far the greater part of its bulk and culminating in the portion exposed above the surface of the sea, was formed by the piling up of successive layers of snow during the period, amounting perhaps to centuries, during which the ice-cap was slowly forcing itself over the low land and out to sea, over a long extent of gentle slope, until it reached a depth considerably beyond 200 fathoms. The lower specific weight of the ice then caused an upward strain which at length overcame the cohesion of the mass, and portions were rent off and floated away. If this be the true history of the formation of these icebergs, the absence of all land *débris* on the portion exposed above the surface of the sea is readily understood. If any such exist it must be confined to the lower part of the berg, to that part which has moved upon the floor of the ice-sheet.

The icebergs, when they are first dispersed, float in from 200 to 250 fathoms; when, therefore, they have been drifted to latitudes of 65° or 64° S., the bottom of the berg just reaches the layer at which the temperature of the water is distinctly rising, and is rapidly melted, and the mud and pebbles with which it is more or less charged are precipitated. That this precipitation takes place all over the area where the icebergs are breaking up, constantly and to a considerable extent, is evident from the fact that the matter brought up by the sounding-instrument and the dredge is almost entirely composed of such deposits from ice; for diatoms, *Globigerinæ*, and radiolarians are present on the surface in large numbers, and unless the deposit from the ice were abundant, it would soon be covered and masked by a layer of the exuviæ of surface organisms.

There is one point in connection with the structure of icebergs which is of great interest, but with regard to which I do not feel in a position to form a definite judgment. It lies, however, especially within the province of a distinguished professor in the University of Glasgow, Dr. James Thomson, and I hope he will find leisure to bring that knowledge and experience to bear upon it which have already thrown so much light upon some of the more obscure phenomena of ice. I have mentioned the gradual diminution in thickness of the strata of ice in a berg from the top of the berg downwards. The regularity of this diminution leaves it almost without a doubt that the layers observed are in the same category, and that therefore the diminution is due to subsequent pressure or other action upon a series of beds which were at the time of their deposition pretty nearly equally thick. About 60 or 80 feet from the top of an iceberg the strata of ice a foot or so in thickness, although of a white colour, and thus indicating that they contain a quantity of air, and that the particles of ice are not in close apposition, are still very hard, and the specific gravity of the ice is not very much lower than that of layers not more than 3 inches thick nearer the water-line of the berg. Now it seems to me that this reduction cannot be due to compression alone, and that a portion of the substance of these lower layers must have been removed.

It is not easy to see why the temperature of the earth's crust under a widely extended and practically permanent ice-sheet of great thickness should ever fall below the freezing-point; and it is matter of observation that at all seasons of the year vast rivers of muddy water flow into the frozen sea from beneath the great glaciers which are the issues of the ice-sheet of Greenland. Ice is a very bad conductor, so that the cold of winter cannot penetrate to any great depth into the mass. The normal temperature of the crust of the earth at any point where it is uninfluenced by cyclical changes is, at all events, above the freezing-point; so that the temperature of the floor of the ice-sheet would certainly have no tendency to fall below that of the stream which was passing over it. The pressure upon the deeper beds of the ice must be enormous; at the bottom of an ice-sheet 1,400 feet in thickness it cannot be much less than a quarter of a ton on the square inch. It seems therefore probable that under the pressure to which the body of ice is subjected a constant system of melting and regelation may be taking place, the water passing down by gravitation from layer to layer until it reaches the floor of the ice-sheet, and finally working out channels for itself between the ice and the land whether the latter be sub-aërial or submerged.

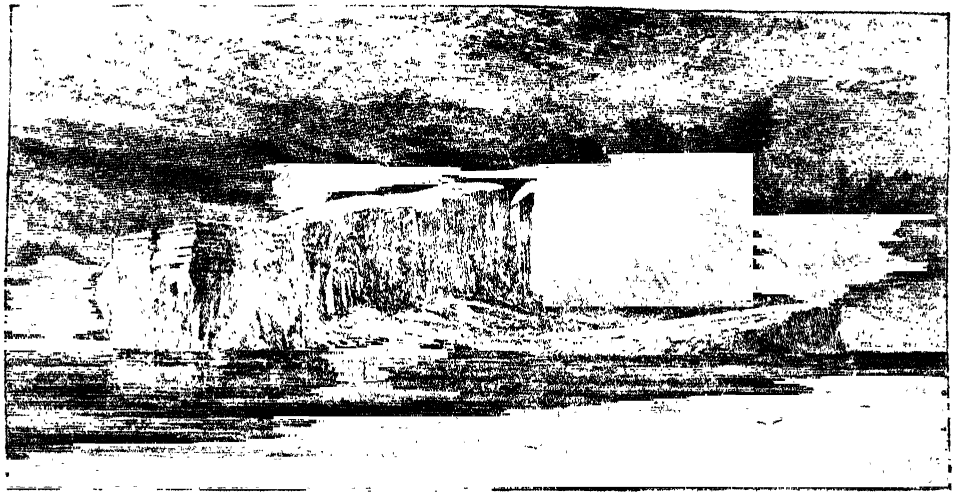

FIG. 4.—Iceberg passed on February 21, 1874. Lat. 63° 3[illegible]′, Long. 89° 6′ E.

I should think it probable that this process or some modification of it may be the provision by which the indefinite accumulation of ice over the vast nearly level regions of the "Antarctic continent" is prevented, and the uniformity in the thickness of the ice-sheet maintained; that in fact ice at the temperature at which it is in contact with the surface of the earth's crust within the Antarctic regions cannot support a column of itself more than 1,400 feet high without melting.

When the icebergs are drifted in the summer a little to the northward—in the meridian of 80° E. to the parallel of 64° S.—they begin to disintegrate very rapidly. The water at the surface of the sea rises to zero and slightly above it, and dashing against the windward side of the berg, partly by its mechanical action, but more by the constant and rapid renewal of the warm water, it wears a deep groove in the face of the cliff. When the groove has cut in so far that cohesion will no longer maintain the weight of unsupported ice, which seems usually to be the case when it is 10 to 15 feet deep, a mass of the cliff falls down, and the weight of the berg being reduced on that side it tilts up more or less and assumes an inclined position; the stratification thus becomes inclined, although it still remains conformable with the plane of the top of the iceberg.

The sea now washes up on the low portion which has been exposed by the tilting of the berg, which it soon reduces to a beautiful curved slope to the bottom of the new cliff, and the process is repeated until by repeated falls of the face of the cliff one side of the berg is so much lightened, that the preponderating weight of the opposite side raises the newly exposed portion out of the water; giving the berg a double outline and the veining a high inclination.

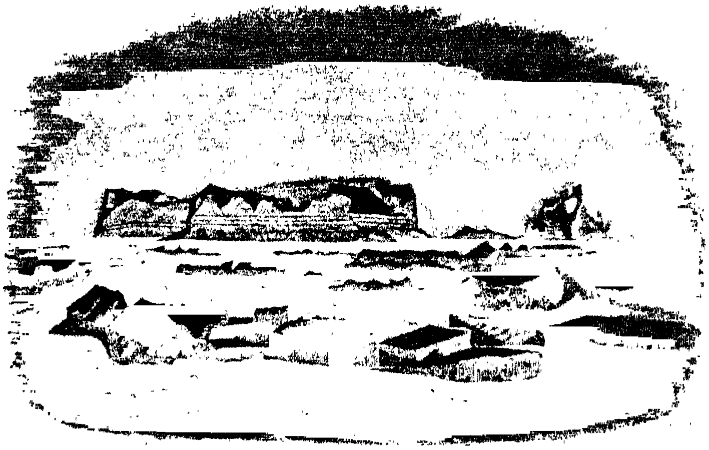

FIG. 5.—February 25, 1874. Lat. 63° 49′ S., Long. 94° 51′ E.

We frequently saw table-topped icebergs with the upper surface very irregular; when that is the case evidence may usually be found from the colour, the closeness of the veining, and other appearances, that it is not the original surface of the iceberg which is now presented to us, but a second surface produced by the cutting away by the sea of an entire story, as it were, of the berg; which athough it had no doubt at one time during the process been greatly inclined, had recovered its equilibrium on the whole of the upper layer having been more or less symmetrically removed. Fig. 3 is a view of an iceberg in which the whole of the upper tier seems to be breaking up and disintegrating under the influence of the air and waves; it is fissured through and through, a large portion has already fallen away, exposing terraces of blue ice previously submerged, and the sea around is cumbered with the fragments. It is easy to see how almost any eccentricity of form may be produced by the irregular action of the waves upon the different sides of an iceberg tilted to different inclinations.

When an accidental hollow or other irregularity on the surface of an iceberg directs the action of the surf on any special point, a cave is speedily formed, and the effect constantly increasing with the deepening of the cavity, the ice is often honeycombed with caverns which penetrate far into the solid berg, and add wonderfully to its beauty by their lovely colouring in shades of cobalt blue, varying with every play of shade and light. The caves are, however, very fatal to the iceberg. From the ice not being thoroughly rigid, whenever the support is taken away from beneath, the layers above bend and give way; vertical fissures are produced which become filled with a breccia of ice and snow, often discoloured by sea-birds; the ice, instead of showing its original uniform horizontal stratification, is distorted into all sorts of anticlinals and synclinals; and fragment after fragment crashes down into the sea.

Fig. 2 gives an idea of the form of a beautiful vaulted berg. The sea was washing through and through it; and as we passed close by, we sat gazing, entranced, at the marvellous beauty of the colouring of the vaults of ice, and the waves, and the snowy spray illuminated by a red setting sun; but our gorgeous iceberg was evidently doomed to speedy destruction. Some glittering pinnacles were the only remains of the buttresses of former arches, and a quantity of *débris* floating round it showed that the whole fabric was undergoing rapid change.

Some few of the bergs which we saw were tilted up to an angle of upwards of 50°, and in various ways—by the inclination of the bergs, by the denudation of successive layers by the action of the sea, and by "dislocations of strata." I believe we saw at various times sections of icebergs to the depth of perhaps 400 feet. All such sections gave simply a continuation of the same phenomenon which we observed in the portion of the berg normally exposed, a gradual approximation of the lines of stratification and deepening of the blue colour.

Sometimes we saw small bergs which were very irregular in form, with all marked prominences rounded off, perfectly clear, and of a deep sapphire blue. These I conceive to be masses of ice from near the base of a berg, which, from extreme shifting of its centre of weight, has turned right over, and exposed the ice near the bottom, in which, by melting and regelation under great pressure, all structure has been lost.

The curious question naturally arises, Shall we ever be able to reach the South Pole? With our present methods and appliances I should think that the answer must be an unhesitating negative. Except possibly somewhere in the region where Ross penetrated, in 1842, to the parallel of 78° to the south of New Zealand, or about Graham Land, where Capt. Dallman, in 1873, continued the explorations of Capt. Biscoe, there seems to be no accessible lead of land; and Ross's southernmost point is upwards of 700, and Graham Land 1,200 miles from the pole. The remainder of the outline of the Antarctic continent appears to be a perpendicular cliff 200 to 250 feet in height, without shelter, and with a heavy pack broken up and kept in motion by frequent gales moving outside it during the greater part of the year, and bounding a vast expanse of glacier surface, a great part of it subject probably to high winds and to almost incessant falls of snow.

We have now learned that the North Pole, if not actually inaccessible, is much more difficult of access than we imagined, even with the long roll before us of the gallant men who have strained through many years the resources of human skill and bravery to the utmost in fruitless attempts to attain the barren issue; and we can only anticipate disasters multiplied a hundred-fold should the South Pole ever become a goal of rivalry among the nations.

C. WYVILLE THOMSON

NORDENSKJÖLD'S EXPEDITION TO THE JENISSEI[1]

THE expedition, of whose plan, equipment, and composition we have already given some account, left Tromsö in the steamer *Ymer*, on July 25 this year, and on the 30th entered Matotschkin Scharr, where they obtained some specimens of Novaya Zemlya salmon. An easy passage was made to the east side, where, during a stay of twenty-four hours, the naturalists did some collecting, dredging, &c. Leaving the Scharr on the 31st, the Kara Sea was at first found quite open, but after a few hours it became so blocked with loose ice in all directions that the *Ymer* was compelled to turn back, and was anchored on the inner side of the promontory which projects from the southern side of the sound, nearly half way between the entrance and Gubin Bay.

Here the sea is rich in varying animal forms, the land bleak and poverty-stricken. The mountains for the most part consist of black clay-slates, probably early Silurian, and grey dolomite beds, in which search was made for fossils in vain. On the other hand, the clay-slate is in many places full of quartz veins with numerous cavities, whose crystalline contents gave occasion to the unfortunate Tschirakin's statement that he had found here a block of stone set full with the most brilliant, beautiful, and valuable precious stones, for which, after his death, he was vehemently censured by his chief, Rossmylov, who sought in vain for the supposed treasure.

In one respect this part of Novaya Zemlya is of great geological interest; for here are to be seen no fewer than six clearly-marked beaches, situated at different heights one above the other, and showing that the land hereabouts has been elevated during the very latest geological period at least 500 feet. With the exception of certain parts of Greenland, where a considerable sinking of the land has taken place during recent centuries, a similar raising of the land has been observed in most other Arctic regions, and this raising of the land has without doubt played a very important part in the great geological changes which have occurred on the surface of the earth since the close of the Tertiary period. For the Swedish observer the phenomenon besides has quite a special interest, inasmuch as attention was first called to it in Sweden more than a century ago, and it then gave occasion to an impassioned discussion between those holding different opinions, which is well known in the history of science.

Matotschkin is surrounded by high, bold mountain ridges and summits, which continue to occupy the interior of the island for more than thirty English miles south of the sound. Farther south the mountain tops disappear completely from the interior, and the land passes into a level high-lying plain, nearly free of snow during summer and sloping gently towards the east coast and the Kara Gate, till it terminates most frequently with a precipitous face towards the sea.

A broad ice-free belt of water having in the meantime been formed along the east coast of Novaya Zemlya, the expedition took advantage of it, and sailed along shore. The greater part of the ice-fields were, however, now quite rotten, and it was clear that they would completely melt away during the remaining part of the summer.

Partly by ice, partly by fog, the *Ymer* was prevented making right across the sea, and it was not till the 12th that the ice-belt was so broken up that they could steam on round White Island, past the Gulf of Obi to the mouth of the Jenissei.

We sighted land here on the 15th, Dr. Nordenskjöld goes on to state, thus exactly a year after the rocks at *Dickson's Harbour* were first seen from the *Pröven*. This was some hours sooner than the dead reckoning promised, which at first was ascribed to the influence of an easterly current in the parts of the Kara Sea we had just traversed. When we came nearer, however, I was surprised to see before me a plain which was unbroken by any "berg-åsar," though I knew, from last year's observation, that an "ås," which was certainly low, but yet perfectly developed, runs over the tundra towards Jewremow Kamen; neither could we discover any of the rocky islands which surround Dickson's Harbour. In the meantime we continued our course up the river along the bank, and after the lapse of four or five hours we obtained a quite unexpected explanation of the circumstances described. For it appeared that the mouth of Jenissei, which is ten Swedish miles (60') wide, is divided into two by an island about five Swedish miles (30') long, which was thought to have been unknown both to Russian chartographers and to the natives. That it has not been before observed clearly depends on its not being visible from the river bank along which the few boats that have traversed this part of the river are believed to have always kept. The navigable water on both sides is deep and free from shallows. This large new island ought clearly to be advantageous for navigation in those regions, as it will form a welcome protection against north-westerly winds and sea for the vessels that may be in the mouth of the river. I mean to name it Sibiriakoff's Island, after the zealous and generous supporter of all this year's Siberian expeditions.

---

[1] Abstract of Prof. Nordenskjöld's Report in the *Göteborgs Handels Tidning*, October 24.

Steaming up the river the *Ymer* reached Mesenkin, which had been appointed the meeting-place with Dr. Théel's party. Here, where the Mesenkin falls into the Jenissei, Dr. Théel expected to obtain some specimens of mammoth skins, which, it was reported, had been washed out of the tundra near this place. Dr. Théel's party, not, however, having arrived at Mesenkin when the *Ymer* reached it, Nordenskjöld himself made an excursion to the locality already spoken of, where the mammoth hide was found. No complete hide was found here, but he succeeded in digging two large and a number of small pieces out of a newly-formed sand-bank at the confluence of the Mesenkin with the Jenissei. The excavations showed that the mammoth remains in question had been newly brought down by the spring floods to the place where they were found from some point situated higher up in the river valley of the Mesenkin, and that the place where the mammoth was originally imbedded in the frozen tundra is to be sought for in this direction.

On August 17 the *Ymer* proceeded up the river, but the water became so shallow, and the navigation by a steamer of such draught as the *Ymer* so dangerous, that Dr. Nordenskjöld resolved to return to Mesenkin. He left his merchandise at Korepowskoj simovie, near Mesenkin, to be taken away next summer by the river steamer. After landing the goods another vain attempt was made to steam up the river, and the *Ymer* was again anchored, this time between Orlowskoj and Gostinoj. The following days were devoted to excursions which yielded interesting information regarding the geology of the tundra, and a very rich collection of the sub-fossil shells, which are found in the sand of the tundra.

By the word *tundra* are denoted, as is well known, the plains of immense extent in Russia and Siberia lying between the boundary of the forest region and the Polar Sea. The ground, at least in the northern parts of the Siberian tundra, is continually frozen at no great depth, but during the summer bears a vegetation of low bushes, mosses, and grass, which yields summer pasture to numerous herds of reindeer, partly wild, partly tame, which wander about on them.

To the eastward of the Jenissei the tundra forms a level or slightly rolling plain, which toward the river has a sloping bank 50 to 100 feet high. In the interior of the country the plain is not interrupted by any very considerable heights, but on the other hand it is intersected at a number of places by deep river valleys, whose steep sides offer fine sections of the earthy layers. It is apparent, on a merely cursory examination, that these for the most part consist of enormous masses of sand and mud washed down by the Siberian rivers. The tundra, however, is by no means a common delta formation. Numerous marine shells imbedded in the sand show that the tundra plain formerly lay under the surface of the sea, and that therefore a considerable elevation of the land must have taken place during the latest geological period. For all the shells imbedded in the tundra sand belong to existing types, the most of which have been dredged up by us from the bottom of the Kara Sea, and which we again find in the post-glacial beds at Uddevalla and Christiana Fjord, and the crag formation of England. All this shows that the tundra has been formed under climatic circumstances very similar to the present, which is further confirmed by the geognostic formation of the beds. It has therefore long been difficult of explanation by the geologist that just in these sand-beds there are found in great abundance remains of the [illegible] animal types that for the present flourish only in a tropical or sub-tropical climate.[1] The evident contradiction which is apparent here has indeed obtained an explanation through the researches of the Petersburg academicians, Middendorff, Schmidt, and Brandt. But there remains here much to clear up, and collections from these regions have, besides, a peculiar interest, from the remarkable circumstance that here in the frozen earth of the tundra there are found not only skeletons, but also flesh, hides, hair, and intestines of animal types which died out many hundred thousand years ago. I therefore, Dr. Nordenskjöld goes on to say, of course, gladly availed myself of the opportunities which offered themselves in making excursions in the neighbourhood of the places where the vessel was anchored. Among the results of our search may be mentioned large pieces of mammoth hide, found along with some few pieces of bone, at the confluence of Mesenkin with the Jenissei; a skull of the musk ox, remarkable for its size, found together with mammoth bones in another tundra valley south of Orlowskoj; a very rich collection of sub-fossil shells, found principally between Orlowskoj and Gostinoj. In addition, various interesting observations concerning the geological formation of the tundra, &c., were made.

During their stay on the Jenissei there was often a dense mist with rain prevailing, but otherwise they were favoured, as a table of observations shows, with warm and summer-like weather. The ground was quite free of snow, and at several places, especially in the tundra valleys, adorned with a variegated carpet of flowers. According to the statement of the inhabitants, however, the former part of the summer in these regions had not been fine, and the preceding winter had been exceedingly severe. The temperature of the water of the river at the surface was almost constantly + 12° to 13° C., and even at a depth of nine fathoms the deep-water thermometer marked + 11·1° C.

As it had been arranged that Théel's party, which, as our readers know, had come overland, should in no case stay so long on the northern part of the Jenissei as to run the risk of missing the last river steamer to Jenisseisk, which this year was to leave Saostrowskoj about September 7, Nordenskjöld resolved to set out on the return journey on September 1. This he did, as Théel's party had not turned up.

The sea, he continues, was at first completely free of ice, and first when we came quite close to the east coast of Novaya Zemlya in 75½° N. lat., a very compact belt of worn ice was fallen in with, which stretched along the coast towards Matotschkin. The course was now set along the ice towards the south to 74° 40' N. lat., where the edge of the ice took a westerly direction, which allowed us, without the inconvenience of being hindered by ice, to steam right westwards towards Matotschkin. A perceptible swell now gave indication of ice-free water. If the course from Dickson's Harbour had been set close past White Island towards Matotschkin we certainly would not have met with a single ice-floe. Even in the northerly way I chose our advance was scarcely hindered by ice but by a nearly constant fog, which compelled us to lie still at night. In this way Dr. Stuxberg, the zoologist of the expedition, obtained a welcome opportunity for dredging and swabbing in the deep channel along the east coast of Novaya Zemlya.

Of all the expeditions which have gone to Novaya Zemlya and the sea surrounding it, there are only three which, before the last two Swedish ones, concerned themselves with zoological, botanical, and geological researches and the collections pertaining to them. These are von Baer's expedition in 1837, Heuglin's in 1871, and the Austro-Hungarian in 1872-74.

As far as zoology is concerned, von Baer brought home from his journey about seventy species of invertebrate animals, Heuglin increased our knowledge of the number of species within some groups, and the Austro-Hungarian expedition within others. But all those collections were from the south-western, western, and northern coasts of Novaya Zemlya. Of the nature of the animal life in the Kara Sea all actual knowledge was wanting till last summer. There was also a current tradition among zoologists, grounded on the knowledge of the immense mass of fresh water which the Obi and the Jenissei yearly carry down, partly also on something at first loosely uttered in literature, which afterwards took the form of axiomatic certainty, that the Kara Sea is exceedingly poor in animals.

The Swedish expedition of 1875 has already dissipated these misconceptions, having brought home from Novaya Zemlya and the west coast of Waygats Island a collection many times richer in species than its predecessors. But in any case it was impossible that the collections which were made during a single summer could be taken as giving so complete an idea of animal life in these regions, as is necessary not only for comparison with the existing fauna of other arctic countries, but also for a complete clearing up of its relation to the fauna in the deposits of the Siberian tundra. It was on this account that I made provision for Dr. Stuxberg accompanying this summer's expedition to Jenissej, and carrying on the zoological work. His researches were rewarded with great success, as appears from the short sketch annexed, communicated by him :—

---

[1] The mammoth, for instance, is looked upon as the progenitor of the now living Indian elephant, but a progenitor considerably larger than his descendant, and provided with an abundant covering of hair.

"During the voyages of 1875 and 1876 to Jenissei and back dredging has been carried on at fifty places in all and at different depths from the beach to a depth of 200 fathoms, and rich and comprehensive animal collections have thus been made. A large proportion of species occur locally, and in quite incredible numbers. Others again are found nearly at every dredging, but in far smaller numbers. The occurrence of the latter is more uniform, consequently distinctive of the territory of the fauna in its entirety. To these belong first of all two species of the genus Idothea (*Id. sabinci* and *Id. entomon*), both well-developed, and it may with reason be said that this genus is characteristic of the Kara Sea; it is the province of the Idotheæ. To the animal forms again which are local in their occurrence belong various species of Mollusca, Hydromedusæ, and Bryozoa, but chiefly all the representatives of the Echinodermata are known to exist here. The abundance of these is sometimes quite surprising, and, what is more singular, where a species occurs in any great quantity, it lives nearly alone, and to the exclusion of all others. This, for instance, is the case with species of the genera Cribella, Stichaster, Ctenodiscus, &c., which here are found in large and well-developed types. Not seldom the swab brought up at the same time hundreds of the same species. Of the beautiful Crinoid *Alecto Eschrichtii* there were obtained many choice specimens.

"But rich as is the Kara Sea in asterids and ophiurids, it is proportionately poor in echini. These have been sought for everywhere without success, except possibly close to the east coast of Novaya Zemlya. This circumstance is the more extraordinary as along the whole of the west coast a species of the family Echinus is one of the animal forms that are most abundant and occur most frequently.

"In two respects the zoological work of this summer has been exceedingly profitable for our museums. It has in the first place added something new in all the groups to the very rich collections made during last summer; it has, for instance, increased the collection of crustacea by 20 per cent. new species, and of echinodermata a large number of types has by oft-repeated swabbing been obtained in an extraordinary collection of specimens. Further, the swab has brought up from the bottom of the Kara Sea two animals specially remarkable and important in a systematic respect. The first was brought up by the swab during last year's expedition, not far from the eastern mouth of Matotschkin Scharr. Then it was found in only a few specimens, now we have collected a considerable number. It is a hitherto unknown holothurioid, differing greatly from most others of the same group by its quite complete bilateral symmetry, but from all by its habitus and anatomical structure, and being singular in its kind inasmuch as it combines characters from diverse classes of animals. It has lately been exhaustively described and delineated in detail by its first discoverer, Dr. Théel. The other remarkable animal is one of the greatest rarities within the animal world. It is an Umbellularia[1] of about a foot and a half in length. It was found in 150 fathoms south of Cape Middendorff, and north of the 75th degree of N. lat.

"From the collections made during the Swedish expeditions it appears that the Kara Sea, far from being so poor as has been supposed, is, on the contrary, distinguished by an animal life rich both in individuals and in types when compared with that which Spitzbergen, Greenland, Iceland, and the Arctic regions of North America have to show. It appears, also, that a nearly uniform marine fauna is found around the pole along the whole coast of Siberia and the polar archipelago of North America. The immense mass of fresh-water which the great rivers of Siberia carry down, does not in any degree determine the composition of the animal life on the bottom of its Arctic Ocean.

"Before the various groups have been worked out by specialists it is difficult to state for certain the number of the lower animal types of the Kara Sea, but it may be put approximately at nearly 500 species, a considerable number, indeed, for a sea that previously was believed to be as poor in species as the Baltic. Such, with the addition of about a hundred species of insects from Novaya Zemlya, whence previously only seven were known, and an extended knowledge of the vertebrate world, is the main zoological result of the researches of the last two Swedish expeditions in these regions."

The *Ymer* made a safe return voyage through Matotschkin Scharr, and on September 18 anchored at Hammerfest. Dr. Nordenskjöld concludes :—

"My stay at Hammerfest and Tromsö I turned to account in collecting information from the numerous walrus-hunters there about the state of the ice in the Arctic regions, and especially in the Kara Sea. I have succeeded in this way in bringing together very abundant materials for a solution, founded on actual observations, of the problem in navigation which lies before us here, and I shall, by and by, make a full statement of the conclusions at which I have thus arrived. Here I will only say that it is my conviction, which is also shared by the walrus-hunters whom I have consulted, that a regular sea-communication between Siberia and Northern Europe during a short season of the year ought not to be attended with greater risks and dangers than seamen encounter on many other waters now yearly visited by thousands of vessels."

OUR ASTRONOMICAL COLUMN

TELESCOPIC METEORS.—In his "Histoire de l'Astronomie pour l'Année VIII.," Lalande, referring to Schröter's observations, states, "il a vu plusieurs fois dans son telescope des petites étoiles qui filent comme un petit trait de lumière très-faible, qui dure 2 ou 3s," and by way of explanation goes on to say that this proves the extension of hydrogen and oxygen many leagues in the depth of the atmosphere; meteors or globes of fire which excite astonishment when they are a distance of some hundred *toises*, become shooting stars when they are distant a league, and telescopic stars at three or four leagues, an opinion hardly favoured by later research.

When occupied in comet-sweeping, or general observation in a dark and pretty large field, it has very often occurred to the writer to meet with objects of the class mentioned by Lalande. A striking instance was afforded one very fine April morning about twenty-seven years since (the exact date, though upon record is not at hand at this moment), when a number of telescopic meteors as bright as stars of the eleventh magnitude passed slowly through the field at intervals of a minute or more, the instrument during the time of observation being directed to different parts of the constellation Sagittarius and lower region of Ophiuchus; the course of these meteors was nearly uniform. Their motion was generally so slow that when caught they could be followed to extinction on moving the instrument. On other occasions he had noticed similar slow-moving meteors, though in less number, and hence was under the impression that there was nothing unusual in the occurrence. But in the summer of 1850, happening to mention the observations of frequent faint slow-moving telescopic meteors to Sir John Herschel, that eminent observer, notwithstanding his long experience in both hemispheres, expressed surprise at the phenomenon, and stated that he did not recollect to have remarked anything of the kind. In 1852 Schmidt published the results of his observations of telescopic meteors between 1844–51, "Resultate aus zehnjahrigen Beobachtungen über Sternschnuppen," p. 165; most of those seen by him were as bright as stars of between the eighth and tenth magnitudes, and generally moved very slowly. Schmidt during these observations was for the most part using a "comet-seeker," the same with which he formed the chart for Hour V. of R. A. in the Berlin series; the writer was invariably observing with the comet-eyepiece on a 7-inch refractor giving a power of about 45.

---

[1] Two specimens of the family Umbellularia, the first of which we have any knowledge, are said to have been found on the coast of Greenland before the middle of last century. After a description first given by Ellis and Mylius, the animal was registered by Linnæus in his "Systema Naturæ," in the year 1758, under the name *Isis encrinus*. What has become of the original specimen is unknown. The enigmatical animal type, as it appeared from the descriptions, has been the subject of many interpretations, till Dr. J. Lindahl, during the Swedish expedition to Greenland in 1871, succeeded in dredging up two specimens of it in Baffin's Bay, and accurately described its interior structure in the *Transactions* of the Academy of Sciences. Individuals of the same genus have since been found, first by the English *Challenger* Expedition in 1873, between Portugal and Madeira, by the same expedition between Prince Edward's Island and Kerguelen's Land, and possibly at other places in the Antarctic Ocean; afterwards by the Austro-Hungarian expedition in 1873, between Novaya Zemlya and Franz Josef Land (the specimen was lost when the *Tegetthoff* was abandoned); again during the present summer by the Norwegian Atlantic expedition off the west coast of Norway, and finally by us in the Kara Sea. It is thus an animal type which is widely distributed, but of extremely rare occurrence.

Perhaps some of the astronomical readers of NATURE may be able to put upon record the dates of other appearances of telescopic meteors in some numbers and with a general uniformity of direction.

Lalande appears to make his reference to Schröter's observation of telescopic meteors with the intention of illustrating the acuteness of vision of the Lilienthal astronomer. Indeed, in the preceding sentence he makes the following extraordinary statement with regard to Schröter:—"Il a une vue privilegiée pour l'astronomie; il voit Mercure en plein jour à la vue simple."

THE COMET OF THE BAYEUX TAPESTRY.—There can now remain very little doubt that the grand comet which astonished Europe in the year of the Norman Conquest leading to a multitude of records in the annals of the time, and forming, with its astonished beholders, the subject of embroidery on the celebrated Bayeux tapestry, was the famous body which now bears universally the name of our countryman Halley. Allowing for the peculiar character of Chinese observations of comets, the account they have left us of its track amongst the stars from the beginning of April to the end of the first week in June, 1066, is well represented by elements not differing more from the actual elements of Halley's comet than accumulated effect of perturbation in eight centuries may well explain. If it is assumed that Halley's comet arrived at its least distance from the sun on March 18, its position when discovered by the Chinese in the morning sky on April 2, would be as they record in their sidereal division "Shih," two degrees south of the equator, and distant from the earth rather less than eight-tenths of the earth's mean distance from the sun. Between this date and June 8, or sixty-seven days after discovery, which is the duration of visibility assigned, the comet would make a grand sweep across the sky from the constellation Pegasus into Sextans between Leo and Hydra, or as the Chinese express it, "through fourteen sidereal divisions from Shih to Chang." The imposing aspect of the comet described in European chronicles and confirmed by the Chinese Annals, wherein it is compared in brilliancy to Venus, and by exaggeration, no doubt, even to the moon, is fully explained by the cicumstances under which Halley's comet must have been observed if in perihelion on March 18. When last seen in China it had receded to 1¾ times the earth's distance from the sun.

METEOROLOGICAL NOTES

RECENT STORMS.—We have already referred to the great cyclone of October 31, which will long be remembered as one of the most appalling catastrophes that has occurred in the history of the human race. The storm-wave advanced over Chittagong from south to north, but most of the damage was done along the shores of the Meghna by a storm-wave which swept seawards from north to south. The details of this and the other features of this great cyclone will be looked forward to with intense interest.—We have also given some account of the storm of wind of almost unexampled violence which broke over Sydney at 9.50 P.M. of Sunday, September 10, and continued with un- [illegible] of Monday. Since as there are good reasons for the belief that the maximum velocity or force of the wind in great storms is frequently understated, it is desirable that the fullest details of the observations from which the velocity of the wind at the rate of 153 miles an hour has been deduced be published in the monthly publication of the Observatory.—A hurricane of great severity and followed by most disastrous results swept over Central America on October 3 and 4. The town of Managua, on the south side of the lake of the same name, and west of Lake Nicaragua, was inundated on the 4th, and 400 houses were blown down by the hurricane. As the flood rose the inhabitants had to betake themselves to the tops of the houses, and many were drowned by the houses falling. The hurricane then passed eastward over Lake Nicaragua and descended over Blewfield, situated on the Mosquito Gulf, and overturned upwards of 300 houses in that town. It was in all probability the same cyclone which was encountered at the same date by the Panama Transit and Pacific Mail Steamer *Costa Rica* about 300 miles to the south-east, near Parita, on the Gulf of Panama, where it was accompanied with a frightful sea-running wind shifting all round the compass and blowing with such a force that the *Costa Rica* had its hurricane deck blown away and the head of the mainmast, maintopmast, and gaff carried off. Later, or from October 17 to 21, Capt. Bremner, of the steamship *Chilian*, reports the severest hurricane he ever experienced at Cayman's Island, to the west of Jamaica, where 170 houses were destroyed and much damage done to fruit trees and other crops.—The list of heavy storms and hurricanes might be increased by including the severe storms reported as having recently occurred in Behring's Strait, wrecking a dozen of whalers, the great gale near Chefoo, in which H.M.S. *Lapwing* was lost, the terrible storms in Madeira and Portugal, commencing on November 11, and the storms of the British Islands a fortnight since, as well as during the present week, with their attendant floods, which in certain districts attained to a height and a destructiveness unknown for many years. The last two months have thus been noteworthy for the violence of the storms of wind which have been let loose, as it were, over all quarters of the globe, thus offering in their salient weather characteristics a marked contrast to the characteristics of the weather little more than a year ago, when we were called to record disastrous inundations occurring in almost all parts of the globe. During the past two months the weather has not only been characterised by the extreme violence of the wind but also by equally unprecedented and violent alternations of abnormally warm and cold, and dry and wet tracks of weather —the connection between which is no doubt a more deeply rooted one than that of mere coincidence.

METEOROLOGICAL OBSERVATORY ON MONTE CAVO.—We are interested to learn, from a letter which appears in *Comptes Rendus*, that P. Secchi has succeeded in establishing a meteorological observatory on the summit of Monte Cavo. This is the highest of the volcanic group in Latium. Its summit rises 953 metres above the sea-level and about 900 metres above the Roman Campagna. The meteorological instruments are placed in the convent, and the monks are charged to make observations. These instruments are a Fortin barometer, a psychrometric thermometer, a maximum and minimum thermometrograph, a pluviometer, and a weather vane. An anemometrograph will soon be added. The isolation of the mountain, which rises about 200 metres above the surrounding volcanic cones, renders it peculiarly well suited for researches in meteorology. In view of the importance of the institution the Government has agreed to defray the expense of installation. The observations are only begun two months; they show, among other things, that the temperature of Monte Cavo is often higher than that of Rome, and that the variations of temperature are less than on the plain. There is another observatory at the base of the cone, at Grotta-Ferrata, in a monastery there also; its elevation is about 120 metres, and it serves for investigating the phenomena of the agricultural region, the most interesting of the environs of Rome, along with another station placed at Velletri, on the other side of the volcanic group.

BIOLOGICAL NOTES

THE PRIMARY ELEMENTS OF THE SKULL.—At a recent meeting of the Cambridge Philosophical Society Mr. Bettany brought forward some of the ideas resulting from Prof. Parker's most recent researches, which will be embodied in a forthcoming work on the "Morphology of the Skull," by Messrs. Parker and Bettany. A fundamental point in researches of this kind appears to be the question what are axial and appendicular elements in the skull. For some years past Profs. Huxley and Parker have regarded the primary rods or *trabeculæ* occupying the base of the forepart of the skull as being the foremost of the series of facial or visceral arches (mandibular, branchial, and the like). In several types, although these *trabeculæ* lie in the true base of the cranium, they are at an early stage more or less parallel with the visceral arches; and certain nerve-relations appeared to show a close similarity between them. But Mr. Parker now believes their facial nature cannot be maintained. They arise in tissue immediately beneath the brain cavity as the vertebræ arise beneath the spinal canal; the temporary flexure of the fore-part of the skull does not make this tissue other than axial. Every relation of the trabeculæ proper is to the nervous centres, and cartilaginous growths continuous with them bound the cranium laterally just like the lateral occipital or vertebral regions. Mr. Bettany also directed attention to the nasal, prenasal, and antorbital regions of the skull as probably showing rudiments of true appendicular parts in the anterior regions of the head. In the discussion which followed, Prof. Humphry cordially welcomed this rehabilitation of the trabeculæ, having never been able to agree with Prof. Huxley that they were facial in their origin. He could not doubt that the bones formed in them, the basisphenoid and presphenoid, were axial in character. He thought that further research would but demonstrate more clearly the vertebral or segmental theory of the skull.—Mr. Balfour thought research was not yet sufficiently advanced for a true estimate of the skull to be formed. Although the trabeculæ might be morphological continuations of the basal cartilages in the hinder part of the skull, yet the greater part of the vertebræ and part of the base of the skull, arose from an unpaired cartilaginous mass surrounding the notochord, while no such element existed in the anterior part of the skull. It appeared very possible that the lateral parts of the cranial floor behind were really equivalent to the base of the cartilages which formed the vertebral arches, and thus the trabeculæ might similarly be regarded as only the basal parts of the continuous lateral wall of the skull.

THE ANATOMY OF THE GORILLA.—Dr. H. Bolau, director of the Zoological Gardens at Hamburg, has recently had the fortunate opportunity of dissecting three gorillas preserved in spirit, with the viscera intact. His results are just published in the "Abhandlungen aus dem Gebiete der Naturwissenschaften," and they add much to our zoological information. The brain is figured by photography from three aspects, Dr. Ad. Pausch describing the convolutions. In all the specimens the liver exhibited the lateral fissures or incisions which are not found in man, the orang, the chimpanzee, or the gibbon, but in all the lower monkeys. This agrees with the descriptions given by Professors Huxley and Flower of the specimen in the Museum of the College of Surgeons; and serves to separate off the gorilla from the rest of the anthropoid apes. The caudate lobe is minute, and the spigelian lobelet of fair size. As in man only among the primates, valvulæ conniventes, the transverse folds of the mucous membrane of the small intestine, so large in the Sumatran rhinoceros, are present, although they are not large. We hope to be able to enter more fully into the results arrived at by Dr. Bolau next week.

THE WINDPIPE IN MANUCODIA.—For a long time it has been known that in the Paradise Bird, *Manucodia*, the windpipe, instead of running straight from the neck into the chest, takes a turn forming a spiral over the front of the breast under the skin before it divides to enter the lungs. M. P. Pavesi has just read an interesting paper on the subject, published in the *Annali del Mus. Civ. di St. Nat. di Genova*, in which he shows that in the three species of the genus examined by him this superficial spiral is only developed in the adult *M. keraudrenii*, in the female of which an irregular and crooked loop only exists; whilst in *M. chalybea* it is only in the male that any superficial loop is found, this being straight and longitudinal, like that in many of the Guans and Curassows of South America. In *M. atra* there is no loop in either sex. M. Pavesi also demonstrates that different specimens of the same species differ slightly in detail.

NOTES

WE announce with sincere regret the death, on Tuesday morning, from malarial fever, o Mr. David Forbes, F.R.S., the well-known Foreign Secretary of the Iron and Steel Institute. Mr. Forbes was only forty-nine years of age. We hope to give a memoir next week.

WE regret to announce the death of Mr. Louis A. Lucas, the African traveller, at the early age of twenty-five. He reached the equatorial provinces in the month of June last, but his escort proving too weak to allow him to penetrate further into the interior, he returned to Khartoum, *en route* for Suez, intending to reorganise his expedition, and proceed by way of Zanzibar to the Congo. After repeated attacks of fever, he left Khartoum on October 26, but died on the Red Sea, near Jeddah, on his way back, having abandoned all idea of further exploration.

CAPT. NARES has been made a K.C.B. There can only be one opinion that by his conduct both of the *Challenger* and Arctic Expedition he has well earned such an honour. The *Alert* and *Discovery* have been paid off, and the crews were entertained at the Mansion House on Tuesday evening.

COL. GORDON has arrived in Cairo, after an absence in equatorial Africa of three years.

A NAIRNSHIRE African Association has been formed in connection with the International African Association instituted by the King of Belgium.

THE just published *Cosmos* of Guido Cora is mainly devoted to Africa. One paper describes the explorations of Antinori, Beccari, and Issel in the region of the Red Sea about the Straits of Babelmandeb, and another contains letters from various members of the Italian Expedition to Equatorial Africa. There is also an address on Italian Travellers in Africa, by Signor F. Bonola, given to the Egyptian Geographical Society.

ACCORDING to Behm and Wagner's just published Yearly Review of the Population of the Earth, the total population of the globe amounts to 1,423,917,000. Of this number Europe claims 309,178,300; Asia, 824,548,500; Africa, 199,921,600; Australia and Polynesia, 4,748,600; and America, 85,519,800. The average density of population of the whole globe is about 28 inhabitants to one square mile of land surface. The density is of course greatest in Europe, where it is 82 per square mile; in Asia, 48; in Africa, 18; in America, 5½; and in Australia and Polynesia, about 1¼. The publication is accompanied by two maps, one showing density of population in India, and the other recent changes in the boundaries of various districts and countries.

Mr. A'Court Smith writes to us from Gurnet Bay that he has recently found two celts about a mile to the westward of the one referred to in Nature, vol. xi. p. 466. They are both of dark flint, one is very rough, and though apparently used, seems unfinished. The other is curved, and chipped very evenly, the flat surface still showing the weathering of the old flint.

We are glad to see that the North of England Institute of Mining Engineers has at last been incorporated by Royal Charter. This institute was founded in 1852, and has done good work in its own important department.

Mr. Herbert Spencer's new volume, the sixth of the Synthetic Philosophy, comprising the first of his "Principles of Sociology," is now ready and in the hands of the binder.

It is intended to issue from the press of the University of Dublin a series of works, chiefly educational, by members of that University. It is expected that the earliest volumes of the series will be the following:—"Lectures on Physical Geography," by Rev. Samuel Haughton, M.D., F.R.S., Professor of Geology; a treatise on "The Morphology of the Vertebrate Animals," by Alexander Macalister, M.D., Professor of Zoology and Comparative Anatomy; and the first portion of a complete edition of the "Letters of Cicero," with a Commentary, by Robert Y. Tyrrel, A.M., Professor of Latin.

A Belgian Geographical Society has been established, with M. Liagre as president. Judging from its rules, it is founded on a comprehensive basis, and is likely to do good work. It will publish a journal.

A new Geographical Society has been founded in Denmark. The Society proposes to organise lectures, and has invited Prof. Nordenskjöld to speak on the Kara Sea and Jenissei, and Prof. Bergrren on New Zealand, where he stayed during a number of years. The Society will issue a geographical magazine.

The deep boring at Rheinfelden, on the Swiss shore of the Rhine, as seen from a report of Prof. Desor, was stopped at a depth of 1,422 feet, after having pierced 200 feet of granite and diorite, and without meeting with the coal-measures which were expected. It was carried out on the system which has already proved successful in the 2,200-feet boring in Bohemia, *i.e.*, by the process of cutting out of the rock a cylinder by means of a diamond crown. The diameter of the bore, which was, until a depth of 660 feet, only 5 centimetres, was afterwards enlarged to 12, being thus the largest diameter used until now in this kind of boring. In a more or less coarse sandstone the boring advanced at an average rate of 15 metres (49 feet) in twelve hours, and proved altogether most successful. A complete collection of cylinders, cut out of the rocks pierced, which are mostly dyas, is now deposited at the Museum of Aarau.

Messrs. Bickers and Son have just published a new edition of Mr. J. E. Harting's "White's Selborne," containing in an appendix the ten letters from Gilbert White to Robert Marsham which first appeared, with notes by Mr. Harting, in the *Transactions* of the Norfolk and Norwich Naturalists' Society. A detailed notice of these letters will be found in Nature, vol. xii. p. 481. They possess great interest, and add materially to the value of Mr. Harting's beautiful edition of "The Natural History and Antiquities of Selborne."

Mr. R. E. Bartlett, of Chelmsford, has sent us an interesting relic of Mr. Robert Marsham, F.R.S., a well-known observer and recorder of natural phenomena of last century. It is a table containing indications of spring, observed by Marsham at Stratton, Norfolk, read before the Royal Society in 1789. The indications consist of observations on birds, insects, flowers, trees, &c., as to the times when first they appeared, or sang, or leafed, &c. The observations extend over from thirty to sixty years, and are neatly and clearly arranged.

A bed of pink coral has been discovered by the captain of the U.S. steamer, *Gettysburg*, on her passage from Fayal to Gibraltar, in lat. 36° 30′ N., long. 11° 38′ W. The least depth found was 30 fathoms, but the captain has no doubt that the coral comes to the surface at some point near the anchorage. Twenty miles west of the bank a depth of 16,500 feet was found. Between this and Cape St. Vincent, 12,000 feet. The bank is rich in valuable coral of light pink shades. Full details of the discovery have been sent by the commander of the *Gettysburg* to the Navy Department, Washington, by mail.

Telegrams have been received from Bahia (Brazil) stating that the *Frigorifique* had crossed the Atlantic successfully with the methylic ether refrigerating apparatus, which worked admirably through the torrid climate of the equator, meat brought from Europe having been found excellent by the Brazilians. More details are sent by letter.

The French scientific papers publish a letter signed by MM. Jacquet, Hovelacque, Mortillet, and others, engaging to give by will their brain, or any part of their body, to the laboratory of the Anthropological Society, so that experiments may be made and useful observations collected. A special club or society has been established for that purpose.

We have received a highly satisfactory Report for 1875-6, of the Dundee Free Library, perhaps one of the best managed institutions of the kind in the kingdom, thanks to its able librarian and curator, Mr. Maclauchlan. An unusually large proportion of the books consulted and lent were scientific, a decided increase being attributed to the University Science Classes in connection with St. Andrews University. In connection with the library a fine museum is being gradually collected, Arctic fauna and flora, as might be expected, being largely represented. We have also received the Twentieth Annual Report on the Sheffield Free Public Libraries and Museum. The libraries are evidently largely taken advantage of, and a very large proportion of the books in demand belong to the department of Arts and Sciences. The Sheffield Museum, which was established some twelve months ago as a Free Public Museum, has lately received the very fine collection of antiquities known as the Bateman Collection, formed by the late William and Thomas Bateman of Derbyshire, and previously stored in Lomberdale House, near Bakewell, where it was almost entirely hidden away, and known by little more than the printed catalogue of it compiled by Mr. Thomas Bateman, and published in 1855. The collection consists chiefly of British antiquities ranging from the Celtic to the Old English period, and is especially rich in Celtic and Roman remains. It also contains many Etruscan, Greek, and Egyptian antiquities of considerable rarity and interest. The public of Sheffield and lovers of antiquities generally, are indebted to Mr. W. T. Bateman of Middleton Hall, Derbyshire, for the opportunity of inspecting and studying this interesting and instructive collection.

At the meeting of the Mathematical Society of November 9 Prof. Smith was chairman only in the early part of the meeting; before the reading of the papers, the new president, Lord Rayleigh, took the chair.

The distribution of prizes and certificates obtained by the students of the Science and Art Classes of the Belfast Working Men's Institutes took place on November 28. These classes are attended by hundreds of persons of the very kind to whom they are likely to do most good, and yearly carry off a large percentage of the prizes of the department. Dr. Andrews distributed the prizes and gave a short address.

The inauguration of the French National School of Agriculture took place at the Conservatoire des Arts et Métiers on Wednesday, December 6. There are about fifty pupils, all of them taking the course of lectures for the first year of instruction. Amphitheatres and classrooms have been prepared for them in one of the courts of the establishment.

At a recent meeting of the United States National Academy, Prof. Henry communicated some additional facts obtained in his long-continued and elaborate researches concerning sound in relation to fog-signals. His principal investigation this year had reference to the divergence of sound, especially as to the phenomenon known as the Ocean Echo. To test the explanation given by Prof. Tyndall, requiring reflection from the air, the trumpet of a siren was turned directly to the zenith. The blast was exceedingly intense, but no echo was heard from the prolongation of the axis of the trumpet, *i.e.*, from the zenith. A loud echo was, however, heard from the whole circumference of the horizon, half of which was on land, the other half on water. This was repeated many times, and always with the same result. In one case a small cloud passed directly across the zenith, from which a few drops of rain fell into the mouth of the trumpet; still no sound was heard from the zenith, although sound continued to be heard from around the horizon. In this case, on account of the divergence of sound, portions of waves in every direction must have descended to the horizon; and as some of these must have reached the plane of the ocean n a path curving inward towards the source of sound, they would, when they reached the ear of the observer in the vicinity of the source, seem as if coming from a point in the horizon, and hence would give rise to the phenomenon of the ocean echo. Rays of sound at different distances from the ear would be reflected from the surface of the ocean, and thus give rise to a prolonged echo. This is in accordance with the fact observed during last summer, that a blast of five seconds' duration gave an echo that was prolonged twenty seconds. That could only be produced by ordinary reflection from a series of surfaces placed at different distances, an arrangement of the material of he atmosphere which (on the doctrine of probabilities) would not be of frequent occurrence.

In an address at the Manchester Literary and Philosophical Society, Prof. Boyd Dawkins made some forcible remarks on he position of museums in Britain. After speaking of the ecessity of museums and laboratories to the student of nature, nd of the few good museums in this country, he said:—"From my xperience of those abroad, I turn to those of our own country with feelings of envy and regret. Here a museum is frequently a arge sort of advertising bazaar, or a receptacle for miscellaneous uriosities unfitted for a private house, or it is composed of an ccumulation of objects valuable in themselves but valueless for ll practical purposes, because they are crowded together, or towed away for want of room. They are generally undermanned, starved for want of funds, largely dependent on casual enevolence, or a burden on the scant resources of the various ocieties. On the Continent, in America, and in Australia, they re as a rule well officered, well arranged, and not dependent on rivate resources for their sustenance. That our museums should e allowed to be such a striking contrast to those of our neighbours and kinsmen is a most singular oversight in the richest, nd, as we sometimes fancy ourselves to be, the most practical eople in the world. With regard to the arrangement of subordinate parts in a museum, that which is now being carried ut in the new Imperial Museum, at Vienna, under Dr. Hochtetter, seems to me the best; to form one lineal series, inorganic objects forming the base, then Palæontological specimens, lustrating the life which has been, and leading up to the illustrations of the life which is now on the earth, Botany, Zoology, natomy, and the like. When this is completed, the Museum t Vienna will present a more perfect and complete history of the nowledge of the earth and its inhabitants than has as yet been presented. In the City of Lyons, which in its commercial aspects resembles Manchester, the collections are lodged in a magnificent building—the Palais des Beaux Arts—supported by the municipality, and are being largely increased by the contributions of local naturalists, who have banded themselves together for that purpose under the title of 'Les Amis des Sciences Naturelles.' There is one point in which the British Government may learn a lesson from the German. When I was in Berlin this autumn I had the pleasure of meeting gentlemen who had been sent by the latter to make collections in the Americas, in India, and in the China seas; and I saw a valuable collection made by German cruisers in the Pacific. Why should not our ships of war, which are to be found in every sea, have orders also to bring home collections from distant stations, and why should not we send out travellers with the same object? With our navy and our wandering instincts, we ought rapidly to outstrip any rivals, and that at a comparatively small expenditure of money."

The Manchester Literary and Philosophical Society possesses a select and valuable library; a catalogue of this, by Mr. Nicholson, hon. librarian, has just been published.

We have received the winter programmes of five Cumberland Scientific and Literary Societies. They appear to us satisfactory, and creditable to the intelligence and culture of the Cumberland folk. The towns to which these societies belong are Workington, Whitehaven, Maryport, Cockermouth, and Keswick, and in some of them, besides lectures by well-known men, and papers by members, regular science classes are to be held during the winter. These and other societies, as we intimated some time since, are formed with the Cumberland Association for the Advancement of Literature and Science, Part I. of the *Transactions* of which is to hand, and contains some papers worth perusing.

A magnificent work on the Yellowstone National Park is about to be published by Prang and Co., Boston, U.S. The description is to be by Prof. Hayden, and will be accompanied by a fine series of chromo-lithographic reproductions of water-colour sketches taken by the artist to the expedition of 1871, Mr. Thos. Morran. The work will be published simultaneously in English, French, and German.

In 1866 the students at the six Russian Universities—St. Petersburg, Moscow, Kasan, Kharkoff, and Odessa—numbered 3,591; in 1871 they were 5,301; but in 1873–1874 there was a large diminution, and in 1875–1876 they were only 4,492. It appears that, generally speaking, Russian students have no resources of their own, and are obliged to give lessons to support themselves. At Moscow many of them are said to be in a miserable condition, principally amongst medical students. Three or four students lodging in the same miserable room is a usual occurrence. From 1870 to 1873 the University registers show that 3,224 students left, having finished their course of studies, but no less than 2,911 were obliged to desist without having taken their degree. A good many scholarships of the amount of from 19*l.* to 38*l.* yearly (which amount it is proposed now to raise to 45*l.*) were founded by Government, and yet more by private persons and institutions; but the number of them is yet far below the number of students who have no other means of subsistence than miserably paid lessons. After all, the Russian students are not worse off than many of the students at the Scottish Universities. A few years ago at St. Andrews it was no uncommon thing for students to cover all the expenses of a six months' session, including 10*l.* for fees, with from 16*l.* to 20*l.*; they would simply have stared had they been spoken of as miserably off.

The additions to the Zoological Society's Gardens during the past week include a Bonnet Monkey (*Macacus radiatus*) from

India, presented by Mrs. Aspinwall; a Macaque Monkey (*Macacus cynomolgus*) from India, presented by Mr. Richard Schott y Larios; a Duyker Bok (*Cephalophus mergens*) from Natal, presented by Mr. J. D. Witherspoon; a Hairy-rumped Agouti (*Dasyprocta prymnolopha*) from South America, presented by Mrs. Booth; a Spring Bok (*Gasella euchore*) from South Africa, purchased; a White-throated Capuchin (*Cebus hypoleucus*) from Central America, three Rough-legged Buzzards (*Archibuteo lagopus*), European, deposited; a Long-nosed Crocodile (*Crocodilus cataphractus*) from West Africa.

SCIENTIFIC SERIALS

Verhandlungen der k. k. zoologisch-botanischen Gesellschaft in Wien, vol. xxv. The following papers are published in this volume: On some new species of *Mycetophilidæ* from the neighbourhood of Sandez (Galizia), by Dr. A. Grzegorzek.—On the structure of the muscular cells and on the general structure of *Mnestra parasites*, Krohn, by Prof. C. Claus.—On some new and some insufficiently known species of *Cecidomyidæ* of the Vienna district, by Dr. Franz Löw.—On the relations of the African and Indo-Malayan bird-fauna, with some general remarks on the geographical distribution of mammals, by A. von Pelzeln.—On Hungarian fungi (third treatise: *fungi hypogæi*), by Prof. A. Haszlinsky.—Description of new and insufficiently known *Phryganidæ and Oestridæ*, by Dr. Fr. Brauer.—Mycological notes, by S. Schulzer von Müggenburg.—*Hemiptera Heteroptera Austriaca*, MM. Maji.—Augusti, 1870, a J. A. Palmén collecta, by O. M. Reuter.—On some new *Lepidoptera* of the South American fauna, by Dr. O. Staudinger.—Second note on the Arachnida-order of *Territelariæ* Thorrell (Mygalidæ Autor.), by Dr. Anton Ausserer. This is one of the most elaborate papers in the volume. On North-American moths, specially *microlepidoptera*, by Prof. P. C. Zeller; this is equally elaborate.—Notes on Adriatic echinoidæ, by Dr. E. von Marenzeller.—On the vegetation-formations of the Taurian peninsula and its climatic conditions, by Dr. A. Rehmann.—Researches on the *Diptera*-fauna of Austria, by Josef Palm.—On the ornithological fauna of Moravia, by F. von Dalberg.—On the occurrence of *Salix babylonica, L., androgyna et masculina* in Austria, by J. E. Hibsch.—Lichenological excursions in the Tyrol, by F. Arnold.—On some species of *Salix* new in the "Wechsel" district (Lower Austria), by E. Woloszczak.—Researches on land-*Isopoda*, by C. von Vogl.—On some species of *Spermophilus*, by Ernst Schauer.—On the fungi-flora of Bohemia, by F. von Thümen.—On the occurrence of short-eared *Arvicolæ* near Vienna, by Prof. L. H. Jeitteles.—On thermal constants and the power of accommodation in the vegetable kingdom, by Prof. H. Hoffmann.—Remarks on some ferns from the island of Celebes, by M. Kuhn.—Botanical excursions in Italy, by Dr. C. von Marchesetti.—Researches on some parasites infecting the hop plant, producing mildew and "kupferbrand" (copper-burn), by Wilh. Voss.—Second paper, containing additional remarks on the *Cecidomyidæ* of the Vienna district, by Dr. Franz Löw.—Researches on *Æolidiadæ*, by Dr. R. Bergh.—New researches on *Phylliliadæ*, by the same.—European *Encyrtidæ*, considered biologically and systematically, by Dr. G. Mayr (this paper occupies some hundred pages).—Muscorum species nova, by J. Juratzka.—Symbolæ ad pteridographiam et Characeas Hungariæ præcipue Banatus, by Dr. V. de Borbás.—On some Lepidoptera, by A. F. Rogenhofer.—Researches made upon leaf galls and their causes on *Vitis vinifera*, by G. von Haimhoffen.—Six years' observations on the first appearances both in the animal and vegetable kingdoms at New Cologne near Milwaukee (North America), by Th. A. Bruhin.—On the flora of Lower Austria (second paper), by J. Wiesbaur.

Poggendorff's Annalen der Physik und Chemie, No. 9, 1876.—This contains the following papers:—Experimental researches on liquid-friction in salt solutions, by M. Sprung.—On the summer rain season of Germany, by M. Hellmann.—Observation of the retardation in the progress of the induction current by means of tuning-fork apparatus, by M. v. Ettingshausen.—On the passage of strong induction currents through liquids, by M. Herwig.—Contributions to electrodynamics, by M. Wand.—On the dependence of the electric conductivity of selenium on heat and light; the photography of tones, by M. Stein.—On the dependence of the specific heat of mercury on the temperature, by M. Winkelmann.—An interesting aërostatic experiment, by M. Reauleaux.—On the theory of double refraction, by M. v. Lang.

THE *Naturforscher* for October, 1876, contains the following papers of interest:—On the specific power of substances in solution, to turn the plane of polarisation, by H. Landolt.—On the uneven surface of meteorites, by M. Daubrée.—On the nature of milk globules and the formation of butter, by F. Soxhlet.—On some phenomena in the combustion of gases, by Herr Horstmann.—Note on the germ-leaf theory in botany, by Herr Famintzin.—On the action of carbon bisulphide as a means for conserving animal and vegetable substances, by Phil. Zöller.—On the absorption of carbonic acid by saline solutions, by J. Setschenow.—On the explosion-limits of mixtures of combustible gases with oxygen or atmospheric air, by A. Wagner.—On the first appearance of the plants now living during geological periods, by Herr de Saporta.—On the deep-sea temperatures in the South Pacific and the circulation of waters from ocean to ocean; speculative remarks based upon the results of the *Gazelle* Expedition sent out by the German Government, by Herr von Schleinitz.—On the chemical composition of leaves, according to the age and species of trees, by P. Fliche and L. Grandeau.—Hypothesis on the nature of the soft aggregate state of matter, by L. Pfaundler.

SOCIETIES AND ACADEMIES

LONDON

Geological Society, November 8.—Prof. P. Martin Duncan, F.R.S., president, in the chair.—Melville Attwood, San Francisco, and R. W. Moore, Whitehaven, were elected Fellows of the Society.—The following communications were read:—A short notice of a new exposure of rhætics near Nottingham, in a letter from E. Wilson, F.G.S., dated November 3, 1876.—Note on the Red Crag, by W. Whitaker, F.G.S.—On the Kessingland Cliff Section, and the relation of the forest-bed to the Chillesford Clay, with some remarks on the so-called terrestrial surface at the base of the Norwich Crag, by F. W. Harmer, F.G.S.—Observations on the geology of East Anglia, &c., by S. V. Wood, jun., F.G.S., and F. W. Harmer, F.G.S., &c. The subjects discussed in this paper were threefold, viz.:—(1) The unfossiliferous sands of the Red Crag. (2) The unconformity between the Lower and Middle Glacial deposits. (3) The mode in which the Upper and Middle Glacial were accumulated. The views of the authors under the first head were similar to and confirmatory of those advanced in the previous paper by Mr. Whitaker; but they pointed out that the Red Crag, which these sands, in an altered form, represent, could not belong to the Chillesford division of that formation, by reason of the casts of shells which had been preserved not comprising any of the more characteristic Chillesford species, and of their including among them forms confined to the older portions of the Red Crag. They also pointed out that the Chillesford Clay had been removed over all the area occupied by these sands by denudation prior to the deposition of the Middle Glacial, which rests upon these sands wherever they occur. The removal of the Chillesford Clay, the authors consider, was due in part, if not in all, to the great denudation between the Lower and Middle Glacial, which gave rise to the unconformity discussed under the second head. This unconformity they illustrate by lines of section traversing most of the river valleys of Central and East Norfolk and Suffolk. These show that such valleys were excavated after the deposit of the Contorted Drift, and out of that formation and the beds underlying it. They also show that the Middle and Upper Glacial have been bedded into these valleys, as well as spread (the middle only partially, but the upper more uniformly) over the high grounds formed of contorted drift out of which they were excavated, and thus generally concealing that deposit, which manifests itself only in the form of occasional protrusions through these later formations, but which they consider constitutes, though thus concealed, the main mass of the two counties. The authors also describe a glacial bed as occurring at various localities in the bottom of some of these valleys, and which in one case they have traced under the Middle Glacial. This they regard as having been formed in the interval between the denudation of the valleys and their subsequent submergence beneath the Middle Glacial sea; and inasmuch as such valley-bed invariably rests on the chalk in a highly glaciated condition, they attribute its formation more probably than otherwise to the action of glaciers occupying the valleys during an inter-glacial interval of dry land. They also suggest that if this was so it is probable that that the forest and mammaliferous bed of Kessingland, instead of being coëval with the pre-glacial one of the Cromer coast, may belong to this inter-glacial interval—that is to say, to the earliest part of it, before the glaciers accumulated in the valleys, and when the climate was more temperate, any similar deposits in these inter-glacial valleys having been for the most part subsequently ploughed out by the action of the glaciers. In discussing the subject under the third head the authors point out the many perplexing features which are connected with the position and distribution of the Middle Glacial formation; and while they admit that as to one or two of these the theory which they offer affords no explanation, they suggest that the theory of this formation's origin which best meets the case is as follows, viz.:—As the country became re-submerged, and as the valley glaciers retreated before the advancing sea, the land-ice of the mountain districts of North Britain accumulated and descended into the low grounds, so that by the time East Anglia had become re-submerged to the extent of between 300 and 400 feet, one branch of this ice had reached the borders of the counties of Norfolk, Suffolk, Essex, Herts, and Bedford, ploughing out and destroying any lower glacial beds that had been deposited over the intervening counties upon which it rested, and over which we ought otherwise, having regard to the depth of the earlier submergence under which they were accumulated, to find them, but do not. The Middle Glacial formation, consisting of sand and gravel, they attribute principally to the action of currents washing out and distributing the morainic material, which was extruded on the sea-bottom by this land-ice; that ice itself, by keeping out the sea over all the country on which it rested, which was then below the sea-level, preventing the deposit of the Middle Glacial in those parts. The termination of this current action was accompanied by increased submergence and by a gradual retreat of the land-ice northwards to the mountain districts, until Britain was left in the condition of a snow-capped archipelago, from which eventually the snow disappeared and the land emerged. To the moraine extruded from the base of this ice and into deep water they refer the origin of the Upper Glacial Clay, the moraine material remaining partly in the position in which the ice left it, and partly lifted by the bergs which became detached from the ice. Such part of it as was lifted was dropped over the sea-bottom at no great distance from its point of extrusion, and in that way the marine shells occurring in a seam of sand in the midst of this clay at Dimlington and Bridlington on the Yorkshire coast became imbedded, the mollusca which had established themselves on the surface of this moraine material having been thus smothered under a lifted mass of the same, which was dropped from a berg. The authors point out that precisely in the same way in which the Middle Glacial is found stretching out southwards and eastwards beyond the Upper Glacial Clay in Suffolk and in Herts, and is succeeded by such clay both vertically and horizontally, so does the earlier-formed part of the Upper Glacial Clay, or that with chalk *débris*, stretch southwards beyond the later-formed part, or that destitute of such *débris*, and is succeeded by it, both vertically and horizontally. This, they consider, shows that the Middle and Upper Glacial deposits, which constitute an unbroken succession, were due to the gradually receding position of the land-ice during their accumulation, the sequence being terminated with the Moel Tryfaen and Macclesfield Gravels, which were accumulated during the disconnection and gradual disappearance of the ice, and while the land still continued deeply submerged.

Anthropological Institute, November 14.—Col. A. Lane Fox, F.R.S., president, in the chair.—The president read a paper on the Black Burgh Tumulus, Dyke Road, Brighton, explored by him in 1872. This tumulus, about two miles from another opened in 1856, which contained the amber cup, bronze dagger, &c., now in the Brighton Museum, was found to contain towards the centre a layer of charcoal 1′ 10″ below the surface, and extending to a radius of 20 feet. This, on being microscopically examined, was found to be oak charcoal. Portions of ribs of goat or sheep, notched apparently with a flint saw, were found, a piece of British pottery, and in the centre of the tumulus, in an oblong grave 8 feet by 12 feet, was found a skeleton in a crouching position, six feet below the surface, and crushed flat by the superincumbent earth, the face towards the south-east. These remains Prof. Flower ascribes to a female of about 5′.6″; about two feet from the feet lay a fine bronze dagger 4″ in length, with the rivets for attaching it to its handle. A curious food-cup with peculiar ornamentation on one side, and also two small discs of metal, apparently rivet-heads, together with a quantity of small flat beads, originally strung together, were found. These objects belong to the time of interment. Two flint scrapers were also found near the body. The chief peculiarities of this find are the presence of a dagger with a female skeleton and the curiously-ornamented food-cup. The president then read a paper on the exploration, in 1875, of the ditch and tumulus in Seaford Camp. In the ditch at 1 foot below the present surface were found one or two pieces of mediæval pottery, then Romano-British at about 3 feet, and below this chalk rubble evidently filled in, till the original bottom at 7 feet was found. The tumulus inside the rampart was examined, and a large flint scraper and a piece of British pottery were found at 2 feet. Below, at a depth of 3 feet 5 inches, five flint saws and more British pottery were found, also fragments of a flint hammer and a polished flint celt, originally 5 inches long, but broken into three pieces; one of the edges was chipped to make a new edge. The flint hammer was formed from a sea-worn flint pebble. The flint celt had evidently been fractured three or four times at the place of interment. Scrapers and fragments of pottery and a broken but well-shaped barbed arrow-head were also found. No trace of bone was found.—Mr. F. G. H. Price, F.G.S., then read a paper on excavations in the Romano-British cemetery at Seaford, Sussex, by himself and Mr. John E. Price, F.S.A. The authors described the cemetery and the cuttings they made in it. The surface soil, extending to a depth of about 3 feet, contained large quantities of flint scrapers, flakes, and fragments of pottery. Several urns were met with at a depth of 3 feet 6 inches from the surface, which contained, in addition to the usual calcined bones, thin iron nails with large heads, flint flakes, and bronze fibulæ. The objects found in the above excavations were exhibited, and a discussion on the three papers took place, in which the president and others joined. Maps and sections illustrated the papers.—Photographs of a so-called horned man from Akim were exhibited by Mr. Hay per Mr. Francis Galton, F.R.S.

Physical Society, November 18.—Prof. G. C. Foster, president, in the chair.—The following candidates were elected members of the Society:—Major W. Malcolm, R.E., Prof. J. M. Purser, Dr. W. Francis, Mr. G. Johnstone Stoney, and Mr. D. MacAlpin.—Mr. Tylor read a paper on the cohesion and capillary action of films of water under various conditions. The author endeavours to eliminate the action of all forces except that of gravity by immersing his "valves" in water. The models which he exhibited consisted of glass tubes about 3 inches in diameter and 6 inches high, filled with water and containing each a piston, which, on being raised, was capable of lifting by cohesion a heavy mass of metal, the nature of the surfaces in contact differing in the several instruments. From experiments with them he concludes that the time during which a heavy valve can be supported depends upon the size of the surface of contact, the difference of pressure within and without the moving parts, and the smoothness of the valve. On the contrary, dry bodies, such as Whitworth's surface planes, will adhere for an indefinite period. Mr. Tylor considers that the supporting of a body in water is due to a difference of pressure in the water itself, and he adduced Giffard's injector as showing that such differences can take place. He has also studied the form assumed by a drop of water at a tap, and considers that when a fly walks on a ceiling its weight acts in the same manner as the heavy valves in the models exhibited.—Prof. Shelley exhibited some of Sir Joseph Whitworth's surface planes and gauges, and showed their bearing on the subject.—Dr. Stone then projected on to the screen the spectra produced by the diffraction gratings, which he exhibited at the last meeting of the Society. When received on a screen at a distance of about 25 feet they showed bright bands in the red and violet, after transmission through a strong solution of permanganate of potash. Mr. Clarke has since ruled for him gratings on the backs of right-angled prisms, and Dr. Stone has cemented, by means of glycerine, or oil of cassia, gratings on glass and steel on such prisms. The lines were two thousand and three thousand to the inch.

Institution of Civil Engineers, November 21.—Mr. George Robert Stephenson, president, in the chair.—The paper read was on the fracture of railway tires, by Mr. W. W. Beaumont, Assoc. Inst. C.E.

Victoria (Philosophical) Institute, December 4.—Mr. C. Brooke, F.R.S., in the chair.—It was stated that the Society now numbered 713 members.—A paper on the Egyptian myth of Ra, by Mr. W. R. Cooper, was read.

Cambridge

Philosophical Society, November 6, 1876.—Mr. J. W. L. Glaisher made a communication to the Society on a formula of Cauchy's for the evaluation of a class of definite integrals.—Prof. Hughes exhibited three series of specimens in illustration of the mode of (1) formation, (2) weathering, and (3) fracture of flint, the first two being selected chiefly with a view to the last. He produced proofs that the supposed faulted and re-cemented flints were generally only flint that had irregularly replaced jointed chalk, the formation of the flint being arrested by the joints. In the case of the banded flints he exhibited and distinguished two kinds—one in which infiltration had taken place all round the outside, often a good test of the drift origin of certain fragments; and the other in which a difference of texture, due generally to some included organism, had determined and limited the areas over which infiltration had produced bands of colour. He pointed out that these differently coloured included portions, whether banded or not, affected the fracture, as they also depended upon the texture of the flint, but that the bands themselves had little or no influence upon the fracture. He then drew attention to a series of specimens which showed that when flint or other material of a similar texture was struck by any object such as a round-headed hammer, so that the blow was symmetrically distributed over a small area, a bruise was produced which on weathering flaked off all round a small cone having an angle at its apex of about 110°, and that when the whole had flaked away a smooth basin was left. But if, and only if, the blow was sufficiently intense to break the flint up, this cone was found to truncate a larger cone whose apex had an angle of about 30°. He pointed out that modifications of this double cone structure explained the "rings" and "bulb of percussion" which were appealed to as evidence of the direction of blows on which arguments were founded as to the origin of some stone implements.

Paris

Academy of Sciences, November 27.—Vice-Admiral Paris in the chair.—The following papers were read:—On the crystals of magnetic oxide of iron formed during the roasting of a spathic ore, by M. Boussingault.—On various works of hydraulics, executed by the ancients in the environs of Rome, by P. Secchi. He notices, shortly, an inverted siphon aqueduct at Alatri, a complete system of drainage there, mode of supplying purified rain-water to the town of Segni, filtration through porous soils, mode of cooling the *aqua tepula*, and of removing carbonate of lime from water. P. Secchi has found the spring which furnished the *aqua tepula*; its temperature is 17° to 18° C. in winter, and it cannot have been over 18° when the ancients used it; this shows the extreme slowness of cooling in the interior of the globe.—On a remarkable fall of hail observed at Grotta Ferrata, by P. Secchi. The hail cloud appeared like an immense ball of cotton or wool, and it advanced with a whirling movement from south-east to north-west. The first rain drops were very large, at least 1 cubic centimetre. The hailstones which followed were formed of groups of crystals like those of quartz gathered round an irregular mass of ice. These groups weighed 40 to 60 grammes; certain blocks at Marino, 300 grammes. Round grains, with concentric layers, were very few. P. Secchi thinks electricity not the cause but the effect of hail.—On the composition of gun-cotton, by Prof. Abel. This refers to a note by MM. Champion and Pellet.—On a new electric repulsion and its application to the theory of comets, by MM. Reitlinger and Urbanitzky. Operating with air, oxygen, hydrogen, nitrogen, &c., in Geissler tubes, they got, under pressures of 2 to 8 mm., the usual attraction in the luminous column when the finger, or any conductor was brought near; but, pursuing the rarefaction further, a repulsion. Using a tube like an electric egg, the nebulous light was like the tail of a comet, and the repulsion was very strong, and manifest at a great distance.—On the portative force of horse-shoe magnets; extract from memoir by M. van der Willigen. To saturate his magnets he places them vertically with their poles on those of a Ruhmkorff coil, the circuit of which he opens and closes several times; the magnetism in the magnets then reaches its maximum, even supersaturation. After the last opening, he slides the magnet carefully towards the edges of the polar planes of the electro-magnets. Then he puts the well-cleaned support before the magnet, inclining the latter slowly. Immediately the support has joined the magnet, the latter can be removed without effort; its portative force is then nearly a third greater than the permanent portative force of M. von Wetteren's best magnets. This state of supersaturation he makes the starting-point of his researches.—Researches on the vitality of the eggs of phylloxera (second paper), by M. Balbiani. He examines the action of alkaline sulphocarbonates, sulphide of carbon, and empyreumatic products.—Treatment of phylloxerised vines, by M. Boiteau.—On a question of ballistics, by M. Astier.—On the determination of groups formed of a finite number of linear substitutions, by M. Jordan.—On the application of methods of mathematical physics to the study of bodies terminated by cyclides, by M. Darboux.—Construction for a point of the curve of intersection of two surfaces with the centre of the osculating sphere of this curve, by M. Mannheim.—Explanation of actions at a distance; gravitation, electric actions, by M. Picart. He explains all phenomena by matter in motion.—Crystals of gallium, by M. Lecoq de Boisbaudran. These are octahedra truncated at the base; the angles indicate a clino-rhombic form.—Note on the determination of sugars by means of titrated liquors, by M. Perrot.—Second note on testing for fuchsine in wines, by M. Fordos.—Researches on the real origin of nerves of general sensibility in the medulla oblongata and the spinal chord, by M. Pierret.—On the physiological action of temperatures below zero, on silk-worm grains, by M. Duclaux. To the limit, at least, of − 10°, the effects produced on the grain by lowering the temperature are comparable in their nature, and differ only in their intensity; this intensity does not increase or decrease regularly with the temperature, but presents a maximum for a certain point of the thermometric scale. This physiological zero of the grain is probably a little above the ordinary zero.—On the structure of the optical system in crustaceans, by M. Chatin.—Synoptic table showing the distribution of fossil molluscs in the Tertiary layers of the Paris valley, by M. Meunier.—On a crystallised silicate of baryta obtained artificially, by M. Pisani.—On the study of the barometer, by M. Wickenheimer. 1. The mean of barometric observations, made at any hour for all the days of the month, gives a constant number, whatever the hour. 2. The barometric height passes two maxima and two minima daily. 3. The annual barometric mean is constant for all hours of the day.—Observation of descending trombes, made at the Cape of Antibes, November 21, 1876, by M. Ferreri.

McLENNAN'S STUDIES IN ANCIENT HISTORY

Studies in Ancient History, Comprising a Reprint of Primitive Marriage. By John Ferguson McLennan, M.A., LL.D., Advocate. (London: Quaritch, 1876.)

THE learned and ingenious author of "Primitive Marriage" has in this volume republished that excellent work, appending to it his paper on "Kinship in Ancient Greece," which originally appeared in the *Fortnightly Review*, and some essays, in which he discusses Bachofen's "Das Mutterrecht," Morgan's work on Relationships, Sir Henry Maine's views on the constitution of the Ancient Irish Family, and the chapter on Marriage in my "Origin of Civilisation."

Bachofen supposes that in the first stage of the development of the family marriage was unknown; and his theory is that at length the women, being by nature nobler and more sensitive than the men, and impelled moreover by strong religious aspirations, combined to put an end to this system, and to introduce marriage. For this an appeal to force became necessary and was successful. The result of the victory, moreover, was that the women claimed and established a superiority over the men; they were the heads of the family; after them the children were named; through them the rights of succession were traced, and they even exercised a political as well as a domestic supremacy. At length, however, men reasserted their original supremacy; they reconquered the first place in the family and the state, established their right to the inheritance of property, and to confer their names upon their children. Mr. McLennan considers that Bachofen's "methods and results are equally unscientific;" he points out that the system of inheritance through females is really no evidence of female superiority, but arises partly from marriage not being monogamous, or such as permitted the certainty of fatherhood, and partly also, he considers, from the fact of women not yet living in their husbands' houses. At the same time he fully concedes to Bachofen the honour of being the first to point out that a system of kinship through mothers only had generally preceded that through the male line.

Nor is Mr. McLennan more disposed to accept the theory of Mr. Morgan, which indeed he characterises as a "wild dream, not to say nightmare, of early institutions." Mr. McLennan supposes that in Mr. Morgan's opinion his tribal organisation was an institution intentionally designed to prevent the intermarriage of near relations. In support of this he quotes the passage in which Mr. Morgan says: "It is to be inferred that the tribal organisation was designed to work out a reformation with respect to the intermarriage of brothers and sisters."

From this and other passages a previous writer in this journal, and I myself, had supposed that Mr. Morgan regarded the steps in his system of development as arbitrary and intentional.

Nor do I even now see how we could have arrived at any other conclusion. Mr. Morgan has, however, explained that this is not his theory, and I am not therefore sure whether either Mr. McLennan or I thoroughly understand his view. The solution which he has given, however, of the origin of the family in Mr. McLennan's opinion—"failing to explain the phenomena must sink below the level of reasonable guessing, to which level indeed it must have sunk even had it explained the phenomena, if by any other set of mere conjectures the phenomena could be equally well explained."

Mr. McLennan himself considers that the earliest form of marriage (if indeed it can be so called) was that still prevalent amongst the Nairs of Malabar, in which one wife was married to several husbands not necessarily related to one another. Under this system the idea of relationship naturally took the form of kinship through females. Family property went ultimately to the daughters of their sisters; a man's heirs being in the first place his brothers, and subsequently his sister's children. From the Nair system was, in Mr. McLennan's opinion, gradually developed (in many cases through an intermediate form anciently prevalent in Britain) the Thibetan species of polyandry, in which the sons of a house took one wife between them. This change eventually introduced kinship through males. It involved the breaking up of the primitive form of the family, and led in time to the transference of the government from the mother to the father. After this the practice of monandry arose, the younger brothers making separate marriages, and thus Thibetan polyandry died out, leaving behind it the Levirate, that is to say, the obligation of brothers to marry in turn the widow of a brother deceased, a custom which the Old Testament has rendered familiar to us. The Levirate next died out, and thus the family slowly assumed the form to which we are accustomed. It will thus be seen that the keystone of Mr. McLennan's system is the practice of polyandry, which, indeed, under his theory is a necessary stage of the development of the family relationship. I cannot, however, regard polyandry as having been a general and necessary stage in human development. I have therefore suggested that individual marriage rose out of capture. That just as a warrior converted to his own use the animals which he captured, and made slaves of the men, so he made a wife of any woman whom he admired, the capture giving him a right which the other men of the tribe did not share. This view, indeed, seems so natural that I wonder it had not been before suggested; and I observe that one or two recent writers have treated it as a recognised and well-known fact, whereas it cannot at present claim to be more than an individual theory which none of the authorities on such a question, such as Mr. Darwin, and Mr. McLennan himself, have as yet accepted. Mr. McLennan, indeed, denies that my views are "in the least degree probable," and if such a question could be decided by authority, I should at once bow to his decision. Such, however, is not the case, and I will only say that, before my work was published, I had foreseen and weighed as carefully as I was able, the objections which Mr. McLennan has now brought forward; and that I then thought, and still think, that I have satisfactorily replied to them. The fundamental objection which Mr. McLennan urges I did not indeed expect him to allege. Like Bachofen, I commence with a time when marriage did not exist. Mr. McLennan, however, replies:—"Sir John Lubbock has not only failed to show that the initial stage of his scheme ever existed, but has failed also to make it in any the least degree probable that it ever existed" (p. 449).

I will, in reply, content myself here with quoting one authority only for the existence of my first stage, an authority for whom I have the highest respect, namely, Mr. McLennan himself:—"I conceive," he says, "that marriage was at first unknown;" in fact, the initial state in his system is practically the same as in mine; the differences between our views lie in the subsequent stages.

In his last essay Mr. McLennan discusses Sir Henry Maine's views on the Ancient Irish Family. The question is very complex, and those who have not Sir Henry's work by their side for reference will not find this chapter very easy to follow.

The Irish family "was anciently divided into four groups known as the 'geilfine,' 'deirbfine,' 'iarfine,' and 'indfine' divisions. . . . . Within the family seventeen members were organised in four divisions, of which the junior class, known as the 'geilfine' divisions, consisted of five persons; the 'deirbfine' the second in order, the 'iarfine' the third in order, and the 'indfine' the senior of all, consisted respectively of four persons. . . . . If any person was born into the 'geilfine' division, its eldest member was promoted into the 'deirbfine,' the eldest member of the 'deirbfine' passed into the 'iarfine,' the eldest member of the 'iarfine' moved into the 'indfine,' and the eldest member of the 'indfine' passed out of the organisation altogether."

A complete family therefore would be composed as follows:—

Indfine.	Iarfine.	Deirbfine.	Geilfine.	
A_1	A_2	A_3	A_4	Fathers and brothers.
B_1	B_2	B_3	B_4	Sons and first cousins.
C_1	C_2	C_3	C_4	Grandsons and second cousins.
D_1	D_2	D_3	D_4	Great-grandsons and third cousins.
			E_4	Great-great-grandsons.

On many points, however, Mr. McLennan dissents from the views of Sir H. Maine.

Sir Henry Maine, for instance, says, "The Brehon writers speak of its (the geilfine division) consisting of a father, son, grandson, great-grandson, and great-great-grandson, which is a conceivable case of geilfine relationship, though it can scarcely be a common one." Mr. McLennan, on the contrary, thinks that "it was, actually or constructively, the only one—when the division was full—*i.e.*, when all its possible members were in being."

Again, Sir Henry Maine considers this strange arrangement to be "a monument of that power of the father which is the first and greatest landmark in the course of legal history."

Mr. McLennan entirely dissents from this, and indeed after discussing Sir Henry Maine's views with ingenuity and erudition, he concludes that the objections he has brought forward "are fatal to Sir Henry Maine's account of the system. He has failed to throw light either on its purposes or its principles. He has made no single feature of it clear in the light of Roman law, and, after all his ingenious reasonings, has left its main features as mysterious as he found them."

Whatever conclusions on these subjects may ultimately be arrived at, everyone who reads Mr. McLennan's book must feel that he brings to the inquiry an immense amount of learning, and has stated his views with great ingenuity. All students of early history will hope that he may have leisure and health to pursue his studies.

JOHN LUBBOCK

OUR BOOK SHELF

Science in Sport made Philosophy in Earnest. Edited by R. Routledge, B.Sc., F.C.S. (London: Routledge and Sons, 1877.)

THE title of this book at once recalls Dr. Paris' "Philosophy in Sport made Science in Earnest." The author, however, tells us in his preface, that the reason he has adopted so similar a title is that his original design was to re-edit Dr. Paris's well-known, but now antiquated, book; finding, however, that mere patchwork would not bring the book into harmony with the present state of science, he determed to treat the subject afresh, and the volume before us is the result of that determination. The inversion of the title is, we think, wise, though some will object to the use of the word philosophy in the sense meant by the author, and will contend that the term physics should have been employed. The graver question is whether, under any circumstances, science should be taught by sugar-sticks. Our own opinion is decidedly against all books of this kind, and there can be little doubt intelligent children prefer not being trapped into the study of any subject, but like work openly and honestly put before them. Such books as the original editions of Mrs. Marcet's "Conversations in Chemistry," or the altogether admirable "Chapters on Sound," and other little books by Miss C. A. Martineau, are the best kind of reading to put into the hands of children who wish to learn the rudiments of natural knowledge. Nevertheless, Mr. Routledge has done his work extremely well. Those who like science and a story running together, will here find a trustworthy, clear, and accurate introduction to the study of physics. W. F. B.

Mushrooms and Toadstools. By Worthington G. Smith. (London: Hardwicke and Bogue.)

THIS is a reprint in a separate form of the descriptions illustrative of two large sheets of figures of edible and poisonous fungi, with the addition of two key-plates. Not having been written and designed for separate publication, it is consequently not so complete as it might otherwise have been, and we doubt whether by itself it will prove of much service in the discrimination of good and bad fungi. Mr. Worthington Smith may be accepted as a safe and trustworthy guide, having himself suffered on one or two occasions from reckless indulgence in doubtful species; he is desirous of sparing others like sufferings, and approaches the subject fortified by experience. In conjunction with the plates this key is admirably suited to fulfil its purpose; as a separate work, we doubt whether the author himself would feel wholly satisfied. If this reprint leads to a wider acquaintance with the diagrams, which ought to find a place in every schoolroom, its reproduction in this form will fully justify the step which the publishers have taken. M. C. C.

Between the Danube and the Black Sea; or, Five Years in Bulgaria. By Henry C. Barkley, C.E. (London: John Murray, 1876.)

THIS book has not been written to take advantage of the interest in Bulgaria excited by the present crisis. Mr. Barkley really spent twelve years in Turkey—the first five commencing shortly after the Crimean war, and the other seven at a subsequent period. He was employed as an engineer in connection with a Bulgarian railway, and had ample opportunities of becoming well acquainted with the country and the people. These opportunities he took good advantage of, and in the volume before us has recorded his impressions and adventures in simple and interesting style. It is a valuable feature that Mr. Barkley's sojourn in Turkey was not made during recent events, and his narrative is not written with a view to advocate one side or the other in the present unhappy conflict. He saw the Bulgarians in what may be called their normal condition, and had no reason to be prejudiced for or against any section of them. He saw much to condemn and a good deal to praise both in Christians and Mohammedans, but little that was praiseworthy in Turkish officials, "from the Governor-General to the hangman." The work contains much information on the Bulgarians, their characters and ways, and will be found both interesting and instructive.

The District of Bákarganj; its History and Statistics. By H. Beveridge, B.C.S. (London: Trübner and Co., 1876.)

THE publication of this work is somewhat opportune, for under the reformed, if not improved, spelling of the title, our readers will no doubt recognise the district of Backergunge, which, with other districts at the mouth of the Hooghly, was recently overwhelmed by one of the most disastrous cyclone-waves on record. Mr. Beveridge is magistrate and collector of the district, and as such has had a good opportunity of becoming acquainted with it. He has evidently also read a great deal on the subject, and the result is a work which ought to take a good place as a local history. Mr. Beveridge describes the physical features of the district, its antiquities and early history, the pergunnahs and sunderbunds, treats of Government estates, land tenures, the inhabitants, productions, and manufactures. The second part refers to the several departments of the administration, education, &c. This district, from its low-lying position at the top of the Bay of Bengal, has been peculiarly subject to the inrush of the wave which accompanies cyclones. Until the recent catastrophe the great event in the history of the district was an inundation, evidently caused by a cyclone-wave, which occurred in June, 1822. According to contemporary account, 100,000 persons lost their lives, and as many cattle; but this must pale before the recent catastrophe, and henceforth October 31, 1876, will be the black-letter day in Bákarganj. Mr. Beveridge's book will be found to contain a great deal of really valuable information, and if every district in India were treated in a similar manner, we should possess a library of information of the greatest value. The volume contains a good map of the district.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*]

Sea Fisheries

PROF. NEWTON has sent you a long reply to my criticism of his Address to the British Association; and although it is exceedingly inconvenient to me, as I believe it is also to him, to continue the discussion at the present time, I must ask you for space, as soon as you can spare it, to point out as briefly as I can, how little progress my friend has yet made in his subject. He was good enough to show me his reply before he sent it to you, and I then told him I should have to meet him on every point in it. Nevertheless he sent it for publication, and as the subject appears to me to be one on which the public should not be misled, I am compelled to ask space for some comments upon it.

The Minutes of Evidence given before the Commission, consisting of 61,831 questons and answers rather frighten him, and he turns to the Index for help. Without a careful study of the evidence the Index is practically useless for my friend's purpose, as I told him. And some knowledge of the habits of sea-fish will be exceedingly valuable in enabling it to be understood. The Index is not a *précis*. There is intrinsic evidence in Prof. Newton's reply that he framed it, I think I may say solely from the Index, and not from the evidence; his tables of increase and decrease, and calculations of the number of questions and answers relating to each, are obviously so, and the value of his arguments may be judged of accordingly. To show what his tables are worth I will take two or three entries in them for examination. "Bream" is the first, and that fish is said to have increased. This is the only entry relating to bream in the whole Index. Bream are common fish on very many parts of our coast; they often congregate in large numbers, sometimes on one part, sometimes on another; they happened to have been unusually numerous off Hastings just before the Commissioners were there, and the fishermen accordingly recorded the increase. But there is not the slightest reason for believing bream were then more abundant than usual on our coasts generally than the reverse. "Brill" has two entries, both in the decrease column. In one case the evidence is that of fishermen in Start Bay, who used the sean nets within half a mile of the beach, and who were furious against the Brixham trawlers for sometimes working in the Bay; the said trawlers, up to that time, and for the twelve years since, finding no falling off in the supply of brill. The other case was at Liverpool, where brill was mentioned, among other fish, by the Inspector of the Fish Market, as having diminished. He made the remarkable statement that not 1 per cent. of sea-fish of all kinds was brought to the market in 1864 compared with what had been taken there twenty years before. As the number of fishing-boats had increased during that interval, and the price of fish was, if anything, rather less, owing to the large supplies sent by railway from the east coast direct to the fishmongers' shops, and not going into the market, it is very clear that if the fishermen were getting a living from the 1 per cent. in 1864, they must have been making at least 100 times as much money twenty years before, which is an absurdity. "Cod and ling" come next. Here my friend had better look to his arithmetic. There is no doubt that cod, and haddock especially had fallen off at many of the inshore fishing grounds. They are both species which have fluctuated very much in numbers in many places, the haddock in particular making its appearance in abundance for a season or two, and then becoming very scarce; or they have left places where they were abundant for years together, and again unexpectedly returned. The last report I had from the north-east coast of England, just three years ago, was that the line fishermen were doing well, and their only complaint was of the scarcity of mussels for bait. But it was along this coast that the great outcry against the trawlers arose in 1863, which led to the issue of the Sea Fisheries Commission; and a great deal of the evidence given there was such as might have been expected under the circumstances.

It will be difficult to treat the next entry seriously, but I will try to do so. In a table professing to show the increase or decrease of the fishes with which our markets are supplied, he notes one particular kind as having decreased, and he counts the two instances as helping to prove that our sea fisheries are on the high road to ruin. Those persons who have even but a very slight acquaintance with sea fishing will be rather surprised to hear that the fish whose end is approaching is nothing less than the "dogfish!" one whose utter extermination would gladden the hearts of the fishermen from the Shetlands to the Land's End, and from Dingle to Dover. Hordes of these predatory and mischievous fishes roam round the coasts of the British Islands; sometimes they swarm in one place, sometimes in another. In the herring season the destruction they have caused to both fish and nets has been such that the fishing where they were has been almost entirely stopped for nights together, and the long-liners also suffer severely from them. They are said to have seriously interrupted the Yarmouth herring fishery this year; and the official report for 1875 from the coastguard at Killibegs, in Ireland, states that the dogfish had so much increased that Donegal Bay had, on several occasions, been apparently cleared of fish by them, and that the nets were constantly full of them. It may be well said that happy is the country whose dogfish are decreasing! Would that I could believe they were becoming scarce in our own!

Prof. Newton has evidently been taken in by a heading in the Index, thus—"Dogfish, consumption of." The explanation is as amusing as it is simple. In Morecambe Bay some of the fishermen catch the dogfish, and after skinning it and removing the head and tail, send it under the name of "Darwen Salmon" to the Blackburn and Preston weavers, who are the only persons who will buy it. This is the only case I ever heard of in which the hated dogfish was not knocked on the head and thrown overboard whenever there was a chance of doing so.

Had I space at command I could enlarge on these tables, but

I think I have said enough to show how much dependence can be placed on them.

We now come to the "process of extinction of animals." Here my ingenious friend should be on safe ground. His argument is, as I understand it, that a species first becomes scarce on the borders of the locality or area where it is found in most abundance. Let me apply this rule to the herring. That fish is only met with when it shows tolerably near the coast—on what I presume he would call the "borders." Can he tell us where the herrings go after what is called the herring season, when they disappear—where the great herring centre is? Fishermen have a vague way of answering this question by saying that they go into deep water, which strictly means somewhere out of sight. Has Prof. Newton evolved more than that from his inner consciousness in his study at Cambridge? That he had given five minutes' attention to the practical study of the habits of the herring—to its life-history, before he gave his Address to the British Association at Glasgow, I venture to doubt very much. The apparent abundance of any fish depends very much on the success of the fishery for it; but many things may and do interfere with that success. It is only within the last very few years that evidence, apparently of great importance, has been obtained, pointing to a relation of the temperature of the sea to the depth at which the herrings swim, and consequently to the chances of their coming within reach of the floating drift-nets, or otherwise. No one can say, with any confidence, why fish are taken abundantly by drift-net or line in one week, or even day, and very few in the next. It may appear very well for Prof. Newton to talk of the consideration of our sea-fisheries being "fraught with unusual difficulties," but he disposes of the question as if it were one of no difficulty, by saying, in his Address, that "it is highly necessary to impose some limitation upon them"—the sea-fisheries. This implies, as plainly as can be, that, notwithstanding the "unusual difficulties," he has quite made up his mind on the subject.

Again, he says, "I have found that the grumblers among the fishermen commonly assign some specific cause for their complaints, be that cause real or imaginary. Their assignment of any cause is purely a matter of opinion with them." Is not Prof. Newton aware that very many of the fishermen who gave evidence before the Commissioners stated these matters of opinion simply as matters of fact? The history of the trawling question is quite sufficient to prove this. He then says, "Their statements [those of the fishermen] as to the increase or decrease of fishes relate to a matter of fact within their knowledge." Does he know the meaning of "conflicting evidence," for which he gives a separate column in his tables? If one fisherman says fishes are increasing in a district and another says they are decreasing, are they both to be considered as speaking of a matter of *fact* within their knowledge?

In the matter of the extent of the inquiry under the Sea Fisheries Commission, I must keep my friend to the point. My stated objection to Prof. Newton's address was that in it he clearly spoke of a decline as a fact, and of the Sea Fisheries Commissioners being unable to find any remedy for it—"There was nothing to be done with our Sea Fisheries but to leave things alone." No possible refuge under the expressions in his Address will prevent this meaning being obvious.

I now come to this statement:—"It is quite compatible with an increased *supply* of fish that there may be an actual decrease in the *stock* of fishes." It may be so; but as, at all events, in the important drift-net and line-fisheries, the capture of the fish depends entirely on their chancing to come in the way of the nets or baits, and there is no hunting them down as there is with game on land, the probability of such a case does not appear to be very great. Of course, Prof. Newton will admit that the converse proposition is equally sound—that a decreased supply of fish may be compatible with an increased stock in the sea. There may be millions of herrings in the British seas without our fishermen finding them out; in fact, there must be, for it is only during a certain season in each year that the fishermen meet with them, and, as they will themselves admit, "luck" has then a great deal to do with it.

The "practical mischief likely to result" from such agitation as his Address might stir up is this—the fishermen may fear some new regulation for the size of mesh they use in particular fisheries, and be afraid to order new nets of the old pattern when they are urgently wanted, as was the case in 1863; for a mile and a quarter of herring nets, or two miles and a half of mackerel nets, are very much more costly articles than the comparatively small nets used for salmon-fishing in the rivers. The salmon fishers, as it is, are sufficiently bothered with inquiries and alterations of bye-laws.

Prof. Newton can find no new facts in my book on "Deep-Sea Fishing," supporting my belief that our sea fisheries are not falling off; but I may mention that I have shown from official returns that since the Commissioners reported, there has been a vast increase in the number of the most important class of fishing-boats, used respectively for the trawl, drift, and line-fisheries; and I believe most people will consider that when, for years in succession, more money is invested by the fishermen generally in boats and gear—by the persons who Prof. Newton says know more about fishing matters than he does—and the general supply to the markets does not fall off, but the contrary, there is not much evidence of the stock of fishes in the sea becoming exhausted. That the fisheries at particular places have fluctuated is well known, and if we knew more about what affects the movements of fish, this might perhaps be explained.

The reason why the fishermen were so much in favour of the Sea Birds' Preservation Act was simply because the congregation of sea birds over the shoals of fish often told the fishermen when their fishing was likely to be successful. Prof. Newton, I believe, was anxious to prevent certain species of sea-bird having the protection of the Act, but, unless I am greatly mistaken, he was strongly in favour of the general principle of the Bill. What particular species of fish is devoured by any particular species of protected sea-bird does not affect my argument; but I may suggest that the protected gulls are surface-feeders, and mackerel, herrings, pilchards, and sprats, besides plenty of young fishes of other species, are commonly considered as surface-swimmers. The collection of gulls over the shoals of fish is spoken of by the fishermen on many parts of our coast as one of the "appearances of fish."

The last point to be considered is Prof. Baird's Report on the American Sea Fisheries. Prof. Newton says the decrease of these fisheries on the Atlantic coast of America is therein treated as a fact beyond denial. He is quite correct here; but he adds that "'overfishing' is unquestionably assigned as the chief cause of that decrease."

I have Prof. Baird's Report for 1872 and 1873 now before me. I must content myself with a few extracts from it. Among other fishes he mentions, Prof. Baird gives a good notice of the alewife or fresh-water herring, and speaks of how valuable it has been in attracting the deep-sea fishes to the shores; he points out how the alewife has diminished, owing to the dams in the rivers preventing the alewives proceeding up to their spawning grounds some way from the sea, this fish having much the same habits as the salmon and the shad. As a consequence the myriads of young fish which used formerly to come down to the sea are now not to be met with at the mouths of the rivers. He goes on to say, at page 12:—"It would, therefore, appear that while the river fisheries have been depreciated or destroyed by means of dams or exhaustive fishing, the codfish have disappeared in equal ratio. *This is not, however, for the same reason, as they are taken only by the line, at a rate more than compensated by the natural fecundity of the fish.*" (The italics are mine.) At p. 60 Prof. Baird says, after speaking of the value of the alewife as food for salmon, trout, and other freshwater fishes: "It is in another still more important connection that we should consider the alewife. It is well known that within the last thirty or forty years the fisheries of cod, haddock, and hake along our coast have measurably diminished, and in some places ceased entirely. . . . Various causes have been assigned for this condition of things, and among others, the alleged diminution of the sea-herring. After a careful consideration of the subject, however, I am strongly inclined to believe that it is due to the diminution, and in many instances to the extermination of the alewives" (or freshwater herring). . . . . "We know that the alewife is particularly attractive as a bait, especially for cod and mackerel. . . . The coincidence, at least, in the erection of the dams and the enormous diminution in the number of alewives, and the decadence of the in-shore cod-fishery, is certainly very remarkable. It is probable, also, that the mackerel fisheries have suffered in the same way, as these fish find in the young menhaden and alewives an attractive bait."

Unless Prof. Baird has in a later report expressed an entire change of opinion, I think I am justified in believing that Prof. Newton is as unable to comprehend the question of the American sea-fisheries as he is that of our own.

My friend has told me in his usual good-humoured manner that neither of us will ever convince the other, and I am certainly indisposed to throw away any more time on this discussion; but I may remind those who are interested in it that the question really lies between Prof. Newton and the Royal Commissioners. On the one hand, Prof. Newton, with no practical acquaintance with the subject, knowing nothing of the witnesses or of the circumstances under which they gave their evidence, but taking the Index to the evidence as his sole guide, so completely satisfied himself that the Commissioners had arrived at an erroneous conclusion in believing our sea-fisheries were flourishing that he brought their delinquencies before the British Association. On the other hand, Prof. Huxley (who somehow has obtained the character of thoroughly working out any subject he takes up, so far as he has the means of doing so) and the other Commissioners themselves visited the several fishery stations, ascertained beforehand the nature of the disputes and complaints among the fishermen, and examined and cross-examined the various witnesses. They spent many days separately and together in considering the evidence on the several subjects of their report, and unanimously agreed to this among other conclusions:—

"The total supply of fish obtained upon the coasts of the United Kingdom has not diminished of late years, but has increased; and it admits of further augmentation to an extent the limits of which are not indicated by any evidence we have been able to obtain." E. W. H. Holdsworth

Examinations in Science

May I beg you will introduce to the notice of your readers a grievance urgently in need of a remedy? The grievance is considerable; the remedy simple; and if scientific men will not make it their concern, nobody else will.

A short time ago, when the competitive examination controversy waxed warm, I ventured to enter somewhat fully into the present haphazard system of awarding marks to candidates who competed for posts in the public service. My object then was twofold:—(*a*) to bring facts and figures to bear against the erroneous statements of a few theorists who unfortunately were able to command a great deal of public attention; (*b*) to get fair play for all examinees. My object now, however, is to warn those who advocate the advancement of scientific instruction, that the present faulty method of conducting public examinations (in some quarters at least) tends far more to the depression than to the encouragement of scientific study. Destitute myself of scientific knowledge, and bound to no particular curriculum of instruction, I am obviously not writing from the point of view of a partisan; and if I have joined in the lament of scientific men that insufficient consideration is given in most schools to the teaching of science, it is simply because there are good grounds for the conviction that the higher education of this country is too one-sided.

The point I wish to raise is not whether the grammar and philosophy of science contribute to the training and stimulating of the youthful mind in a greater or less proportion than the grammar and ornaments of the Latin and Greek languages; nor whether so-called technical instruction is being properly administered or injudiciously shelved; but I am asking whether scientific teaching, so however little it be, is adequately encouraged by scientific men in the persons of their public examiners?

Judging from the issues of certain examinations, the candidates for which are drawn from the leading schools, I am satisfied that it is not.

By dint only of considerable pressure are candidates induced nowadays to carry on their school course in science for an additional year or two, so general is the conviction among them that they are merely gambling for marks and that the object of much honest labour will not be attained. In fact, for the particular purposes they have in view, they run the double risk of wasting their time and burning their fingers.

It may, of course, be urged that the ends of science are not furthered by youths who aspire to touch only a modest limit in view of qualifying for public employment; but surely as much may be said of almost every other branch of study. And if this is really the opinion entertained by science examiners, it would be better at once to expunge all scientific subjects from the Government programmes.

But candidates and teachers are concerned only with the rules and regulations that are actually current, and that wiser men have made; and their grievance is that there *is a greater element of uncertainty in the awards issued for science than for any other subject.* Instead of estimating the various science subjects as fractional parts of a wide and comprehensive programme, and of dispensing marks on a fixed and definite plan whereby a given quota of proficiency shall be made to carry the same *relative* weight as a given quota of proficiency in other branches, it would seem that examiners, who, by the way, are constantly being changed, regard their own branch as a distinct entity—set up their own standard of excellence for the nonce—and distribute basket after basket of ducks' eggs among all who fail to reach a very advanced qualifying minimum, forgetting perhaps that meanwhile the classical candidate is receiving his modest or substantial reward according to the character of his work. The position indeed would be pretty much the same as if a classical examiner should announce that no candidate would be entitled to a single mark who did not write a faultless copy of Greek verses! I am prepared to show that this ideal standard has varied to the extent of 50 per cent. in two successive years; nay, more, that science candidates have suffered a loss of 50 per cent. in their marks after an additional year's reading under the best teaching that money can purchase. A case occurred some months ago of a youth who, having won the Huxley and Balfour prizes in Edinburgh, entered his name for an open competitive examination in London. He obtained 64 out of 1,000 marks in his two branches of science, at a moment when from 500 to 600 marks out of a total of 1,500 were being showered upon the classical men. At this particular ordeal "Chemistry" chanced to receive decent recognition, but as this youth's tastes happened to run in another direction he was ignominiously defeated.

Any number of such cases may be enumerated, but perhaps I have said enough to prove that a real grievance does exist.

The remedy is obvious: either to induce the authorities to strike out the words "Natural Science" from their list of subjects, or to arrange for the formation of a committee of science examiners who will devise some plan for fixing, as nearly as possible, a uniform standard, and for distributing marks on equitable principles, after consultation with the classical, mathematical, and other examiners. In default of this I do not hesitate to say that examinees will continue to be trifled with at the most important crisis of their lives; for at these public examinations it is no longer a question whether they gain a scholarship or improve their position at school—it is a question of their future career.

I have yet to state the main point. Setting aside the fact of hardship and injustice, it may be asked how far the present independent and very summary system of dealing with batches of schoolboys can possibly cripple the cause of the technicists who are anxious to press forward the teaching of science. My reply is that science candidates, heartsick with disappointment, will fall out of the ranks and will induce others not to enter them; the belief will rapidly gain ground in the schools that science is "a mistake;" and there is abundant reason for supposing that many a schoolmaster will be only too willing to endorse this opinion. I contend that our public examiners wield the thong that lashes the schools into action, and that we are only just beginning to get fair play for what are called "modern" subjects, but that unless our science examiners apportion their marks in a more just and consistent manner they will simply drive all science candidates "bag and baggage" out of the field. In other words, they will virtually be paying a premium to the schoolmasters for neglecting to carry out the very objects they are clamouring for.

The Rocks of Charnwood Forest

May I be allowed a short space in reply to Prof. Hull's courteous reference to my letter on the Charnwood rocks, for I fear that I have failed to make two points in that sufficiently clear? One was, that as the Borrowdale series of the Lake District and the (Lower) Cambrian series of North Wales are *equally* azoic, no correspondence in time with the latter could be inferred for the azoic Charnwood rocks. The argument from absence of fossils surely tells as much one way as the other; indeed, having regard to the similar petrological conditions of the Borrowdale and Charnwood rocks, I think it is slightly in favour of their correspondence. The other point was, that as Prof. Sedgwick's term Cambrian included the Cambrian and Lower Silurian of the survey, his authority could not be quoted in favour of the (Lower) Cambrian age of the Charnwood rocks any more than of their correspondence with the Borrowdale series, unless it could be shown (I am not aware that it can) that he had definitely correlated them with (Lower) Cambrian beds. Self-Fertilisation in Flowers

DR. MÜLLER (NATURE, vol. xiv. p. 571) and Prof. Asa Gray (vol. xv. p. 24) reflect on your abstract of my verbal remarks (vol. xiv. p. 475) on Browallia in a way not particularly complimentary to me. Prof. Gray admits having read the full report, and yet fails to notice that "February 8," is there given as the date of my remarks. Had he not overlooked this, he would not have wondered that I did not see "Hymenoptera and Lepidoptera of various sorts" visiting them. As reported in the *Proceedings* of the Society, I exhibited fresh specimens in fruit at the meeting of that date, which is about mid-winter with us, when these insects are at rest. The plants were of course grown under glass, and when I say "Browallia is not visited by insects, yet seeds abundantly," I am referring naturally to the experience I am describing. If one be justified in taking an unguarded expression, or even a whole sentence, without any regard to the subject matter of its connection, we might have as many "theories" in science as there are sects in religion, all founded on isolated "texts" in Scripture. It is remarkable that in a paper in which Prof. Gray is commenting on hasty observations, in another he should have overlooked a fact like this. I do not say Browallia is never visited by insects, but I do say that they do not visit them *under such circumstances as I was describing*.

Of the *fact* there is no doubt, of the *interpretation* there may be many opinions; and no one respects an opinion by Prof. Gray, when he carefully considers it, more highly than I. Yet I would respectfully submit, that even though an insect were as careful to avoid the "brush" which almost closes the throat, though it were able to be as careful in finding the chink as Dr. Gray was in his manipulations with the hog's bristle, the obstruction of the mouth in the way it is cannot surely be claimed as an arrangement in favour of cross-fertilisation.

Dr. Müller seems to believe that I do not know that "many flowers have recourse to self-fertilisation when not visited by insects." If he will examine the *Proceedings* of the Am. Association for 1875, p. 247, he will find that I have given him the credit of the observation, and the fact itself such consideration I thought it in justice entitled to. The impression which Dr. Müller's expression warrants, that he has not had the opportunity of reading the numerous observations I have placed on record during the last few years, in relation to this and kindred topics, fully excuses him in my mind for his sharp comments.

THOMAS MEEHAM

On Supersaturated Solutions

IN a paper communicated to the Royal Society last May I described some experiments to show that the open air and the air of ordinary rooms do not generally contain crystals of the various salts which form supersaturated solutions. It has been remarked to me that I did not give the strength of the solutions, so that doubt might arise as to whether the results would hold good for very strong solutions:—The following experiments set that question at rest. I made a very strong solution of sodium sulphate which threw down abundance of anhydrous salt on boiling. When cold a good half inch of anhydrous salt remained at the bottom of the test-tube. Took this into my garden, which is near Bristol. Took up some of the solution in a clean pipette and put drops on the leaves of peonies, which were very dusty, on geraniums, on moss, on the stone coping of Bath oolite, and on the painted woodwork of the railings and garden door. Not a single drop crystallised. Made a drop set quite solid by dropping in earth with the fingers. N.B.—I had been at work with the salt for some time and crystals were probably adhering to my finger. Earth not touched inactive. The drops sank into the moss slowly, remaining quite liquid. Those on the stone were soon absorbed and dried up on the surface; fresh drops put on these remained liquid. Smeared a drop repeatedly with the finger which had been cleansed; inactive, as fresh drops remained liquid on it. Drop on flower-pot, inactive, smeared with finger; when dry inactive to fresh drops. These and other drops on the flower-pot slowly formed a film of 7-atom salt. Stirred the solution with a dry twig picked off the ground, inactive. The drops on the leaves all slowly evaporated, giving the 7-atom salt. Finally, made some of the drops and the original solution crystallise, to prove that they were really supersaturated. These experiments were made both in sun and shade. Weather dry. The test-tube was left open the whole time.

On another occasion I took a flask of sodium sulphate containing a large quantity of the 7-atom salt into the garden in the evening. Put drops on a flower-pot; one only crystallised. Put a lump of dry earth into one drop, and added more solution; did not crystallise. Made a little mud pie by breaking this up with the pipette, inactive; pipette repeatedly inactive in the solution after touching this. Brought a crystal to the earth; crystallised at once all through the mass.

Clifton College J. G. GRENFELL

KARL ERNST VON BAER

SCIENCE has sustained a great loss by the death of Dr. Karl Ernst von Baer, the eminent biologist; he died at Dorpat on November 29, in his eighty-fifth year. Von Baer was born in Esthonia on February 29, 1792, and while yet at the gymnasium became an earnest student of botany. He studied medicine at Dorpat in 1810-14, whence he proceeded to Vienna for the study of clinical medicine, to Würzburg, where he gave special attention to comparative anatomy, and to Berlin, where he studied magnetism, electricity, crystallography, and geology. In 1817 he went to Königsberg as prosector to Prof. Burdach, and two years later he became professor of zoology at the same university. In 1826 he succeeded Burdach in the chair of anatomy, accepted an invitation in 1829 from the St. Petersburg Academy, but returned to Königsberg the following year. A few years later, in 1834 he was again invited to St. Petersburg, where he became one of the most active members not only of the Academy, but also of the Geographical and Economical Societies. Von Baer's writings, marked by philosophic depth, are, on account of their orderly and clear exposition, as attractive as they are generally intelligible. The subject of the origin and development of organic bodies, which had special attractions for him, he did much to clear up. The foundation of his eminence he laid in Königsberg, where he published in 1827 his "Briefe über die Enstehung des Eies," which was soon followed by the important works "Entwickelungsgeschichte der Thiere," and "Geschichte der Entwickelung der Fische." These works, which are yet of great value, have earned for their author the title of Father of Comparative Embryology.

In the summer of 1837 von Baer made a journey of exploration from Archangel to Novaya Zemlya, and his report is still one of the most valuable sources of information upon that island. In 1851 his attention was attracted to the immense Russian fisheries and the irrational methods used. During 1851-6 he investigated the fisheries of Lake Peipus, the Gulf of Finland, and the Caspian Sea, publishing the results of his investigations in a great work in 1859. The name of Baer is connected with more than one improvement in the fisheries, and some important additions were made to the trade, thanks to his efforts. His remarkable work, "Kaspische Studien," has had no rival. It would be impossible to enumerate the various subjects upon which he has thrown clear light in his writings. The laws of excavation of river-beds, the navigability of the Arctic seas, the steppes and forests of Southern Russia, the Glacial period, the Siberian mammoths, the potato disease, were at various times treated by him, and in each department von Baer opened out new and extensive fields of inquiry. His acquirements in zoology, comparative anatomy, embryology, physiology, and anthropology are well known; moreover ethnography, the early history of mankind, archæology, and the science of language will count him among their most eminent students. In his later years, besides various anthropological papers, he published an autobiography (which appeared soon after the fiftieth anniversary—1864—of his scientific career), his "Reden," and "Kleine Aufsätze vermischten Inhalts"

(1864-75). The very valuable publication he undertook along with M. Helmersen, "Beiträge zur Kenntniss des russichen Reichs," numbers twenty-six volumes, and continued to appear until within the last few years. Von Baer continued to work up to the very last, and he has left behind him a large quantity of manuscripts and unfinished works.

Von Baer was undoubtedly one of the most accomplished investigators of the present century. Haeckel speaks of him thus :—"If among living scientific investigators there is one who justly enjoys universal honour and respect it is Karl Ernst Baer; and if classical and in the best sense natural philosophical writers will admire a Coryphæus of to-day, an unsurpassed example of exact observation and philosophic reflexion, let them go to the 'Entwickelungsgeschichte' of this head master of our science." Helmersen speaks of the late biologist as follows in the *St. Petersburger Zeitung*:—"With Baer departs a man such as is rarely met with in any century, a genial man of science and research, endowed with a penetrating critical intellect, with unusual faculty of observation, with perseverance and energy in work. The earth and its inhabitants were the great field of his research, and he brought to his work not only a deep philosophic training, but also an equipment of the profoundest knowledge in several departments of natural science which few of the great spirits of our time have possessed. This great, comprehensive, but profound knowledge, which he to the day of his death continued to increase and turn to use, combined with the determination to trace things to their ultimate grounds and by means of keen and unprejudiced, clearly arranged, and thoughtful observations to discover the truths and the laws of nature, stamp all his works with a monumental character which they will preserve for all time. The widely-known name of Baer is written in large lettters in the book of science and its history."

We hear that a subscription will be opened among all the scientific bodies of which von Baer was a member for the founding of a scholarship in his name, or for any other scientific purpose worthy of the name of the great natural philosopher.

DAVID FORBES

At the comparatively early age of forty-eight the busy life of Mr. David Forbes has been brought to a close. Like his distinguished brother Edward, he has been unexpectedly cut off before much of the immense mass of knowledge he had acquired has been put in a form to be of use to others. He was always looking forward to a time of less active occupation, when he might devote his principal attention to putting on record the results of his many years' investigations. What there may be in the piles of manuscript he has left that will be available for use, there has not yet been time to ascertain. For the last five years the most important papers he wrote were the half-yearly reports for the Iron and Steel Institute, but among his earlier papers there will be recollected "The Relation of Silurian and Metamorphic Rocks in the South of Norway," and "The Geology of Bolivia and South Peru." Alluding to his connection with the Iron and Steel Institute, the organ of that society has just written :—"In his capacity of Foreign Secretary he has, almost from the foundation of the institute, rendered most essential service, and has in no inconsiderable degree contributed to that rapid prosperity which has characterised its operations. His exhaustive reports on the foreign iron and steel industries which appeared in the *Journal* were most valuable, as they embraced everything going on in connection with the iron trade all over the world. The wonderful linguistic accomplishments of Mr. Forbes enabled him to deal easily with the publications of all countries where iron and steel is made. His name was so well known abroad that the leading people connected with the technological features of ironmaking most readily furnished full details of what was going on in each country; and through his influence mainly the institute speedily assumed a recognised position abroad."

Mr. Forbes joined the Geological Society in 1853, and since February, 1871, has been one of the secretaries. He was also a Fellow of the Chemical Society. In June, 1856, he was elected a Fellow of the Royal Society. He had travelled extensively in many parts of the world. All the family of the Manx Forbeses have been great travellers. Dr. Wilson, in his memoir of Edward Forbes, has mentioned many of his relatives who died out of Europe. Mr. David Forbes, as a consulting engineer, had an extensive practice, and was often summoned abroad. His death occurred at his house on Tuesday, December 5, and on Monday, the 11th, his remains were laid in the Kensal Green Cemetery, in the presence of the Presidents of the Geological and Chemical Societies and many scientific friends.

THE GLACIATION OF THE SHETLAND ISLES

In the *Geological Magazine* for May and June, 1870, my colleague, Dr. Croll, first pointed out that the Scotch and Scandinavian ice-sheets probably united on the floor of the North Sea, and thence moved northwards towards the Atlantic. He was led to this conclusion by a consideration of the peculiar direction of the striæ in Caithness, in Shetland, and the Faroe Isles, as well as by the occurrence of marine shells in the boulder clay of the northern parts of Caithness. He showed that the enormous *mer de glace* which pressed out on all sides from Scandinavia forced its way close to the Scotch coast-line, and in virtue of its greater size produced a slight deflection of the Scotch ice, causing it to over-ride portions of the main land. He stated that in all likelihood both the Shetland and the Faroe Isles were over-topped by the Scandinavian ice in its onward march towards the Atlantic.

During a recent traverse in Shetland I obtained evidence which tends to strengthen this remarkable theory. In the north island of Unst, the direction of the striæ, the boulders on the surface, and the stones in the till, clearly indicate that this island was glaciated by a mass of ice moving from east to west. The proofs of continental glaciation, which are comparatively clear in the north, are obscured in a great measure in the main island by the effects of a local ice-sheet. The nature of the boulder clay, as well as the trend of the striæ in various localities, show that the movement of this local sheet was influenced by the general features of the country. In addition to these markings, however, others were found which could not have been produced by ice shedding off the land in the ordinary way. These cross the island, regardless of its physical features, and are often at right angles to the newer set. Lastly, the wide distribution of morainic matter with groups of moraines indicate the gradual disappearance of the local ice-sheet and the presence of small glaciers, where the ground presented favourable conditions for their development.

The islands are dotted over with small lochs; the most of these lie in peat or drift, while others occupy true rock basins. The singular absence of marine terraces ought not to escape notice, as bearing on the recent geological history of these islands, since the voes or sea-lochs are admirably adapted for their preservation.

These observations will be described in detail in a forthcoming paper before the Geological Society.

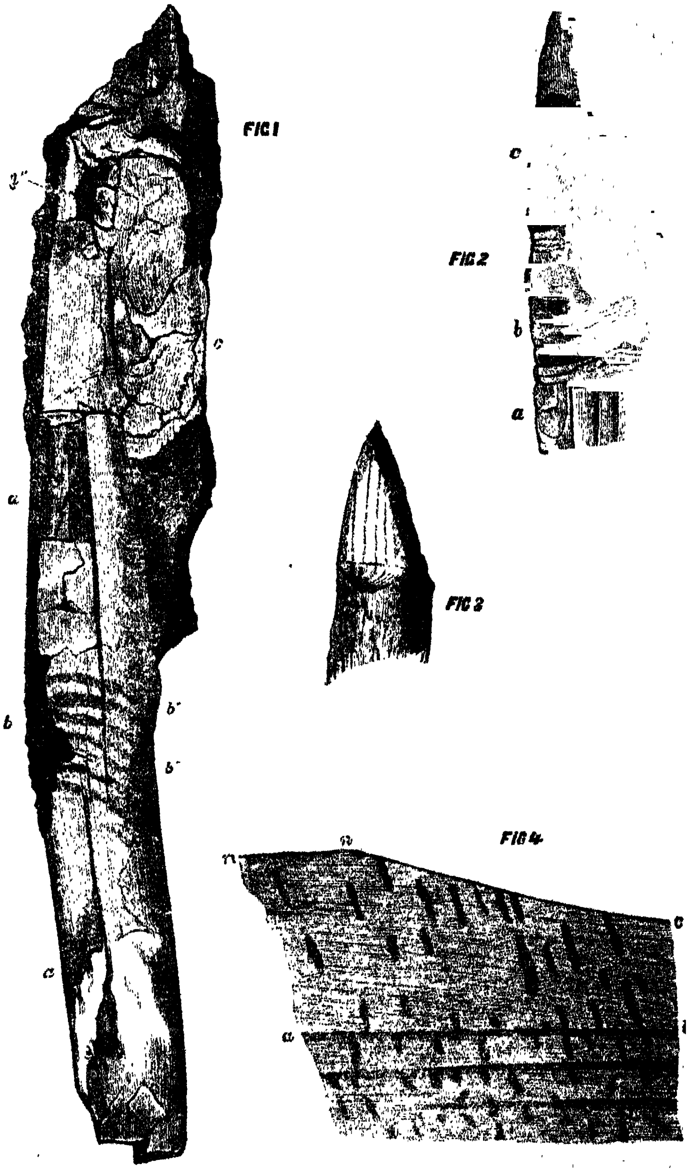
JOHN HORNE

Geological Survey of Scotland, Nairn, N.B.,
November 29

PRIMÆVAL SWITZERLAND[1]

THE veteran Swiss professor, Dr. Oswald Heer, is not more distinguished for his ability and indefatigable industry in original research than he is for his brilliant powers of popular exposition. His admirable work, "The Primæval World of Switzerland," of which both German and French editions have already appeared, has been so favourably received, alike by the scientific and the general public, that we are happy to be able to announce the publication of it in the form of an English translation, adorned with the whole of those numerous and excellent illustrations which contributed so greatly to the value of the book as it was originally issued. A work like the present, in which accuracy of scientific detail is in no degree sacrificed to its main design—that, namely, of producing a succession of lively descriptions leading up to clearly-enunciated generalisations—must be largely dependent not only on the literary skill of its translator, but on his competence for dealing in an intelligent manner with the various branches of natural history treated of; and when we state that the interpreter of Prof. Heer's views to English students is so erudite a naturalist as Mr. W. S. Dallas, the Assistant Secretary of the Geological Society, we have said enough to predispose our readers in favour of the present translation. Nor does a careful perusal of the work serve to disappoint the high expectations we have been naturally led to entertain with regard to it, for both editor and translator have evidently performed their respective tasks in a most skilful and conscientious manner. Neither in respect of accuracy or of elegance do we notice any very serious failures; under the former category, indeed, we only feel called upon to draw attention to a little confusion which exists in some parts of the work with respect to the English and German measures; and, under the latter, to what appears to us to be the rather awkward adoption of the third person, which, however suitable for abstracts or reviews of the writings of an author, seems somewhat out of place when employed in a full translation of one of his works.

To that numerous section of our countrymen who regard "the playground of Europe" as a place only for fashionable lounging or purposeless climbing, Prof. Heer's work may well be commended as opening up new, and to many perhaps, unsuspected sources of enjoyment during their holiday tours. Those who will take the trouble to master the contents of these two pleasantly written volumes—a task demanding no great preparation of preliminary studies—will be in a position to appreciate and follow with ever increasing interest the discussion of those numerous important geological problems, to the solution of which no country in the world affords more important materials than Switzerland. Aided by the carefully arranged collections of rocks and fossils which exist in the museums of all the larger Swiss towns, the tourist would find the means of enabling himself to vividly realise and almost live among the wonders of long past geological periods; and by personal contact with the actual evidences of geological change, his scientific knowledge and convictions would acquire a reality and solidity, which no amount of work in the library could ever communicate to them. Those who will adopt this plan will soon find aroused within their minds an interest and enthusiasm, which will prevent them from ever finding their holiday tour dull; and will be amply rewarded thereby for the necessary preliminary labour. Phlegmatic, indeed, must be the individual who does not find his pulses stirred as he follows in the work before us the life-like delineation by word-painting of the characteristics of ancient worlds, or who does not find the desire awakened in his mind to witness for himself some of the phenomena here described; for even the most indifferent reader cannot fail to catch a portion of the enthusiasm which everywhere glows in Prof. Heer's eloquent pages. But such feelings are only a very feeble echo indeed of the pleasures experienced by the student who has the courage to enter himself within the veil, and to look upon nature and her mysteries face to face.



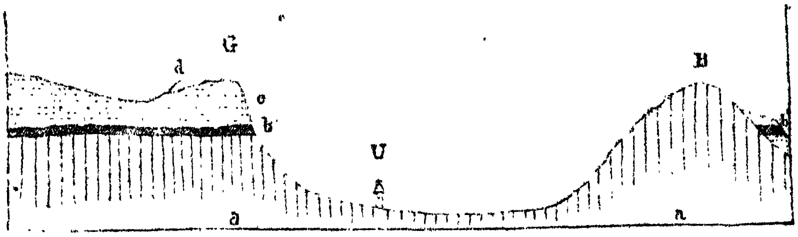
Rods of fir-wood exhibiting marks of cutting and binding, rom the lignites of Wetzikon.

We should, however, be doing Prof. Heer an [illegible] if we referred to his book as being only a popular [illegible] to the geology of Switzerland. To the man of the work will be no less valuable than to the tourist and general reader, for in it he will find an authoritative *résumé* of the results of multifarious studies by one of the most eminent of living palæophytologists; results which otherwise he would be compelled to search for in numerous scattered papers and bulky monographs. Just such a sketch of the general geology of Switzerland as is contained in the work before us, is indeed especially welcome at the present time, from the fact that Studer's admirable "Geologie der Schweiz," is so far behind date. The main features of the Carboniferous, Saliferous, Lias, Jurassic, and Cretaceous formations as displayed in Switzerland, are all very clearly described in Prof. Heer's book; but it is of course in respect to the Miocene—to the elucidation of the characters of the fauna and flora of which his own admirable researches have been more especially devoted—that our author's detailed observations and inferences are possessed of the greatest value and interest. Prof. Heer's general conclusions on such subjects as the physical evolution of our globe, the changes of climate during former geological periods, and the doctrine of descent and Darwinism, are also worthy of the most serious attention.

---

[1] "The Primæval World of Switzerland." With 560 Illustrations. By Prof. Heer, of the University of Zurich. Edited by James Heywood, M.A., [illegible] of the Statistical Society. Two vols. 8vo. (London: [illegible] and Co., 1876.)

We shall not here stop to discuss how far the identification of species of plants, by their leaves alone, is safe or defensible on the part of the palæophytologist. Some botanists, especially in this country, have adopted very extreme views with regard to the work of Heer and others;



5.—Ideal Section of the valley of Utznach (the vertical scale is to the horizontal as 8 : 1). G, Gubel; U, Utznach; B, Lower Buchberg.

demanding that fossil plants, like recent ones, should only be named after an opportunity has been found for studying

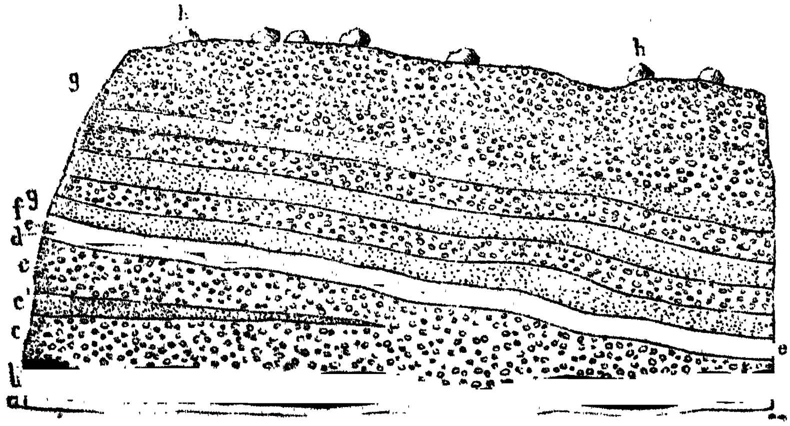
be almost as fatal to the pursuit of the

demand from malacologists that no conclusions should be based on the shelly coverings of molluscs, or from comparative anatomists, that we should reject all identifications based on portions of the skeleton of the vertebrates. It is surely better to make the best of the imperfect materials which we possess—guarding ourselves meanwhile at every point with cautious reservations—rather than to reject it altogether because of its lack of completeness.

Opinions, too, may differ as to the propriety and value of those rather fanciful delineations of scenery in the

is disarmed by the fact that, while a means of arresting the interest of the general reader has been supplied by these rather questionable "landscapes," the real wants of the student have by no means been lost sight of, but are very liberally provided for in numerous other plates and woodcuts of truly scientific character and accuracy.

No time, perhaps, could possibly be chosen as more opportune for the appearance of this work than the present, for attention has recently been very generally drawn to the discovery of certain articles of human workmanship in Switzerland which seem to throw far back the date of the appearance of man upon the globe, and to make him contemporaneous with a portion at least of the Glacial period of that country. The editor of this work has, we think, acted most judiciously in appending to Dr. Heer's book, which contains ample details concerning the characters and relations of the which have yielded these interesting relics, a trans- of Prof. Rütimeyer's memoir in the *Archiv* for 1875, which describes the objects and we cannot more appropriately close this article than by a brief reference to the facts of the case, as detailed in the work before us, illustrating them by several woodcuts borrowed from the same source.



G. 6.—Section of the paper-coal or lignite deposit and pebble-beds, at Dürnten.

That the relics in question are of artificial origin, there can be scarcely the smallest room for doubt. They consist of a number of rods lying side by side in a block of lignite from Wetzikon, in the Canton of Zurich; these rods are of fir-wood, they are converted into true lignite perfectly similar to the surrounding matrix, and are flattened and crushed like the remains of plants, constituting the mass. Careful examination of them shows that the point of one of these rods has been artificially cut (Fig. 1, *a*" and Fig. 3), and that it has been bound round with some flexible material (Fig 1, *b*, *b'*). A second rod exhibits its longitudinally fibrous woody body bound round transversely with a different bark (Fig. 2, *b*). Prof. Schwendauer, who has made a microscopical examination of these interesting rods, confirms the fact of their having been subjected to artificial treatment. He supplies in Fig. 4 an enlarged view, showing how the artificially-produced section cuts across the structure of the wood. We can hardly doubt that we have here portions of a piece of the rude basket-work, the construction of which is among the earliest practised of the arts of savage peoples.

With regard to the mode of occurrence of the Wetzikon lignite deposit, in which these singular remains were found, two woodcuts, which we transfer from Dr. Heer's book, will suffice to make the matter perfectly clear. The first is an ideal section across the Valley of Utznach, which shows the lignites in question (*b*) resting on upturned Miocene strata (*a*) and covered by beds of pebbles (*c*) and erratic blocks (*d*). From this section it appears that a vast amount of denudation has taken place since the formation of the beds of lignite and their being covered up by deposits showing signs of glacial origin, for the outcrop of the lignites occurs at a height of 100 yards above the bottom of the valley. The second section shows the nature of the stratified materials, sand, loam, and pebble-beds (*c*, *d*, *f*, *g*) with which the lignites (*b*, *e*) are interstratified and covered—a number of erratic blocks (*h*), evidently derived from the Alps, surmounting the whole mass.

That these lignites of Wetzikon with their relics of human workmanship are of great antiquity there is the plainest proof; that they are, however, of more recent date than the principal mass of the glacially-derived materials occurring in the great Swiss valley is rendered clear by their undoubted superposition to these deposits, which is seen at a number of different points; but that moraine matter and erratic blocks have been deposited *above* them, either by glaciers or icebergs, there seems to be no room for doubting. We would venture to suggest, in conclusion, however, that the greatest possible caution ought to be exercised in attempting to correlate these Alpine deposits with the glacial beds of our own country.

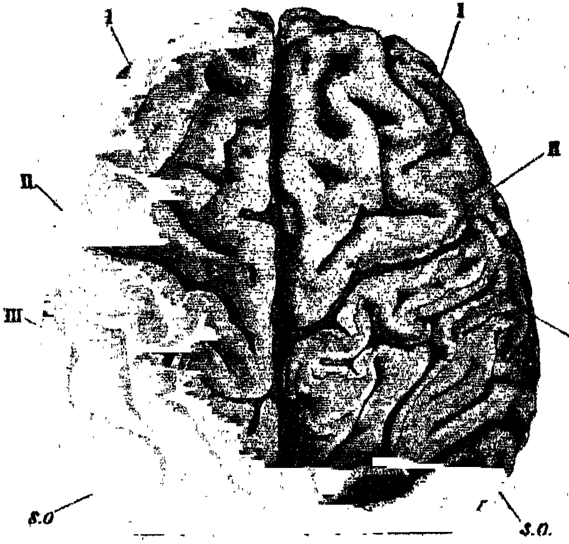
J. W. J.

THE BRAIN OF THE GORILLA

THE anatomy of the brain of the gorilla has been hitherto absolutely unknown. From the valuable photographs published by Dr. Bolau in his recent memoir on the anatomy of the gorilla, which was referred to in last week's issue of this journal (p. 127), I am enabled to give a brief account of its external anatomy, to reproduce the illustrations of its form, and to compare it with the brain of man and the other anthropomorpha. There are three views of the brain, the upper, the outer, and the inner surfaces, figures of which are here given, and a careful description of the sulci, by Dr. Ad. Pansch, is appended.

When seen from above the brain presents a broad ovoid figure, the greatest transverse diameter opposite the supramarginal convolutions, and very nearly two-thirds of its length from the anterior extremity; the frontal lobes are broad, and show a remarkable approximation to the square form of the human brain. In the lateral view it has moderate depth, the arching of the upper surface is but slight, and the highest point would seem to be about midway between the centre of its length and the broadest part. The dimensions are given, length = 100 mm., breadth = 87 mm., and the depth = 70 mm.; but the last certainly includes the cerebellum, for which an allowance of one-fifth may very properly be made, which will reduce the depth to 56. In the orang the three proportions are respectively 100, 78, and 50; in the chimpanzee 100, 84, and 66; in the bushwoman 100, 77, and 62. The breadth of the gorilla's brain here is notable, but in connection with this it may be pointed out that the bushwoman has as great a relative breadth of brain as the European, in whom the numbers are 100, 77, and 69, and that the great and more valuable contrast is to be found in the depth; in the case of the orang (from Dr. Rolleston's paper) it would seem that it must be too low, probably from the flattening that follows removal of the brain from its natural cavity.

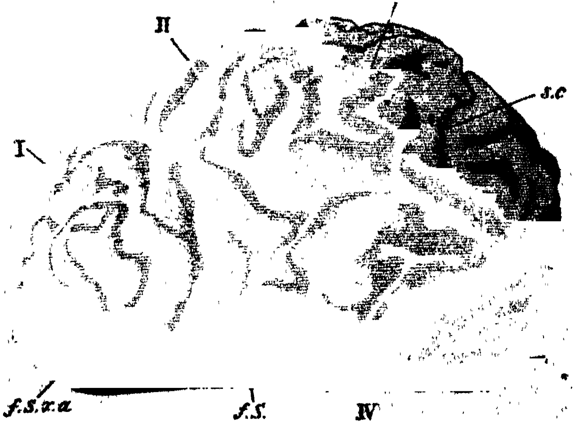
Fig. 1.



Upper view of the brain of the Gorilla. I. Sulcus, præ-central; II. Fissure of Rolando; III. Intra-parietal sulcus; *s.o.* External perpendicular fissure.

Hence conclusions drawn from the shape of the brain itself are from this very circumstance liable to error, and for this purpose casts of the interior of the cranium are the only reliable guides. Referring to those in the Hunterian Museum, that of the gorilla as compared with man is seen to be characterised by want of height, flatness of the vertex, and narrowed frontal lobes; compared with

Fig. 2.



Outer surface of the brain of the Gorilla. I. II. III. *s.o.* as before; IV. Parallel fissure; *f.s.* Sylvian fissure, posterior branch; *f.s.r.a.* Ant. branch of the same.

the orang, in the latter the frontal lobes are more compressed, giving a pointed form to the frontal extremity, and the occipital lobes are larger and more rounded, so that the figure is pear-shaped rather than ovoid; but the vault is decidedly more lofty and better arched; also the orbital concavity is less marked in the orang, so that any deficiency in the lateral development of the frontal lobes might very well be compensated by their downward extension. The chimpanzee and gorilla, however, exhibit a very great resemblance in shape and proportions, though the former has somewhat more compressed frontal lobes, a greater development of the occipital region, and apparently greater width, so that the cast looks more globular than that of the gorilla.

The *corpus callosum* is of good length, but rather thin; its proportion, taking the length of the brain as 100, is 41, and its average thickness appears about one-twelfth of that; in the chimpanzee the length is 39 and the thickness one-eleventh; in the orang, 44; and in man, 40; thickness, one-thirteenth.

The convolutions are strongly marked; in a general view they are slightly more subdivided than in the chimpanzee, but in complexity and asymmetry the orang exceeds the gorilla to about the same extent.

Outer Surface of the Hemisphere.—The posterior branch of the Sylvian fissure extends upwards and ends in the usual bifurcation, nearly at the junction of the middle and posterior thirds of the hemisphere, and almost half of the height from the lower margin; judged by this, the fissure is more oblique than in man, less so than in either orang or chimpanzee. The short anterior limb is very faintly marked in front of the insula, but its ending is distinct, bifurcated, on the outer side of the frontal lobe. The insula has its fore part uncovered in the bottom of the fissure. The external parieto-occipital fissure travels over the outer surface to within a very short distance of the lower margin of the hemisphere; its hinder margin, prolonged forwards, gives rise to a convex operculum in about its lower two-thirds, very much resembling that of the chimpanzee, although somewhat more sinuous. The fissure of Rolando is very oblique, the lower end is remarkably forward, being actually in front of the tip of the temporo-sphenoidal lobe (probably part of this is due to the position of the brain), and the upper end reaches the longitudinal fissure behind the centre of the hemisphere; the angle formed by the two fissures is very little more than a right-angle, 95°.

The length of the hemisphere being 100, the distances in a horizontal line from the anterior extremity to the upper end of the fissure of Rolando, *i.e.*, the extreme length of frontal lobe, being *a*, thence to the parieto-occipital fissure, length of parietal lobe, *b*, and from that to the hinder extremity, occipital lobe, *c*, we get—

	a.	*b.*	*c.*
Gorilla ...	57	29	14
Chimpanzee ...	49	28	23
Orang ...	52	27	21
Bushwoman ...	65	17·5	17·5
European ...	57	23	30

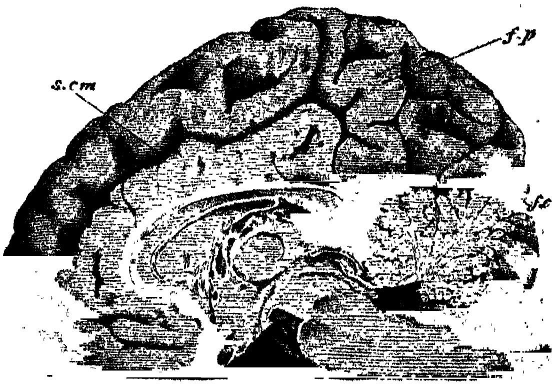
The length of the frontal and the smallness of the occipital lobes are especially noteworthy.

The convolutions of the frontal lobe present their typical arrangement: the ascending frontal is very simple, following in easy curves the fissure of Rolando, and marked only by one slight indentation opposite the superior frontal sulcus; it is bounded in front for the lower half by the præ-central sulcus (Ecker) from which the distinct and strongly-bent inferior frontal sulcus runs forwards to the tip of the lobe. The superior frontal sulcus has its characteristic T shape, the top of the T being placed vertically in front of the upper half of the foregoing convolution, and the second limb sent forwards almost straight for about two-thirds of the distance to the anterior extremity between the upper and middle frontal convolutions. Of the three horizontal gyri, the upper springs by a narrow root from the ascending frontal close to the margin, and shows plainly the indications of the longitudinal division into two; the middle is much narrower, connected to the ascending by a pedicle between the præ-central and superior frontal sulci; and the inferior frontal is well developed, arching over the anterior limb of the Sylvian fissure, and considerably folded. Compared with the chimpanzee, the upper is narrow, the middle and lower larger and more subdivided. The orang throughout the whole lobe exhibits a greater richness of convolution.

The convolutions of the parietal lobe are very definitely and strictly marked off, and at the same time they are decidedly the most developed of the whole brain, far exceeding the chimpanzee, and not inferior to the orang. The intra-parietal sulcus, springing from the Sylvian fissure near its hinder end, runs forwards and then upwards, round the front of the supra-marginal lobule, parallel to the fissure of Rolando, as far as the centre of that, when it turns backwards at an obtuse angle, continues, approaching slightly the longitudinal fissure, and debouches into the external parieto-occipital fissure; from the angle which it forms, the customary prolongation, giving off two or three smaller branches, is sent upwards in continuation of the ascending portion, and dividing the ascending parietal convolution from the parietal lobule almost completely; the interruption to this fissure about its bend which is seen so often in human brains I have observed only in the orang. The ascending parietal convolution is much more developed than the ascending frontal, and it presents a marked indication of a longitudinal fission; the lower end has the usual triangular expansion split into two (superior marginal convolution of Gratiolet). The parietal lobule is large and divided into an outer and an inner portion, the latter showing further subdivisions, in this condition approaching more to the human brain than either orang or chimpanzee. The supra-marginal lobule is more developed than in either chimpanzee or orang, and divided into three portions by a triradiate sulcus, but its proportion and the amplitude of its gyri are much inferior to the human brain. The angular convolution springs from the upper end of the supra-marginal lobule by a narrow bent piece; the descending branch here differs from the chimpanzee and orang in being cut off from the middle temporo-sphenoidal convolution and running backwards into the middle occipital convolution, constituting the anterior boundary of the external parieto-occipital fissure.

The occipital lobe is by no means richly convoluted,

Fig. 3.



Inner surface of the brain of the Gorilla. *f.p.* internal parieto-occipital fissure; *f.c.* Calcarine fissure; *s.cm.* Calloso-marginal fissure.

the three gyri are marked off, the upper being broad and the lower narrow.

The temporo-sphenoidal lobe presents nothing remarkable; the parallel fissure is continuous and simple, running up behind into the angular convolution, where it is cleft, one branch extending downwards parallel to the lower part of the external parieto-occipital fissure, and cutting off the middle temporo-sphenoidal gyrus from the descending ramus of the angular and the second annectent convolutions. The upper convolution is simple, the middle is broader and more folded, the inferior is separated by a well-marked sulcus from the middle.

The first external annectent gyrus is seen issuing from under cover of the operculum, and passing forwards and inwards to the parietal lobule; this is an approach to the orang, in which the gyrus is normally superficial, and an advance on the chimpanzee, in which it occurs only at times. The second does not appear at all; the third is to be recognised nearer the lower margin of the hemisphere and below the lower end of the external parieto-occipital fissure, but the extension of the parallel fissure separates it superficially from the middle temporo-sphenoidal convolution; below this the small fourth appears, uniting the lower occipital and third temporo-sphenoidal convolutions.

Inner Surface of the Hemisphere.—The calloso-marginal fissure pursues its usual course and turns upwards opposite the hinder end of the corpus callosum, sending a branch backwards between the convolution and the quadrate lobule; it is interrupted opposite the anterior extremity of the corpus callosum by a small gyrus, a very frequent condition in human brains; from it a few small indentations pass up into the marginal convolution. The callosal convolution is simple: at the fore part there is a hint of the longitudinal division which obtains here sometimes in man, and it is more broken up when it passes under and is joined by the quadrilateral lobule. The marginal convolution is larger and more divided, but both of these are simpler than in the orang. The quadrate lobule is divided into about four small gyri, and is much larger than in the orang, where the calloso-marginal fissure opens into the surface very near the parieto-occipital, and the lobule is almost obliterated. The internal parieto-occipital fissure does not join the calcarine below, so that a distinct inferior internal annectent convolution is present, and at the upper end the upper internal annectent convolution can be seen coming out of the fissure and joining the upper posterior angle of the quadrate lobule. The calcarine fissure is usual, so also is the fissure of the hippocampus. The occipital lobule is divided into three gyri transversely by two furrows running the upper from the parieto-occipital, and the lower from the calcarine fissures nearly across; this is in marked contrast with the arrangement of the human brain where the gyri run from apex to base, being subject, however, to great variety. The gyri on the under surface of the occipital and temporo-sphenoidal lobes cannot be seen.

The resemblance between this brain and the chimpanzee's is striking both in its shape and the arrangement of the convolutions, so much so that Gratiolet's description of the latter would serve also for many parts of the gorilla's brain. The chief points of difference between the two are mainly in favour of the gorilla, *e.g.*, the greater length and breadth of the frontal lobe, a greater development of the middle and lower frontal and of the parietal convolutions, especially of the supra-marginal lobule and the appearance of the first external annectent gyrus. On the other hand the chimpanzee appears to have some advantage in the important point of greater vertical height. On the whole, the comparison seems to indicate a development of the chimpanzee type of brain and to give it a higher rank than that.

In one particular character it approaches the orang, the partial appearance of the annectent convolution, but the differences in shape, the more perfect operculum, the lesser complication of the frontal and occipital convolutions and the greater symmetry far outweigh the resemblances and denote its proper position as with the chimpanzee, although somewhat nearer the orang than that.

Gratiolet placed the gorilla with the baboons by reason of its elliptical form and the supposed want of development of the frontal and great excess of the occipital lobes; but we see now that of all the anthropomorpha the gorilla is characterised by the most extensive frontal lobe and smallest occipital; in addition to which the richness of the convolutions and the breadth of the frontal region also separate it farther from the baboons than the chimpanzee.

It is certainly open to great doubt whether this diminution of the occipital lobe is at all an ascensive step in the cerebral conformation, in fact, the comparison of the respective proportions in the bushwoman and the European points distinctly in the opposite direction; and it is to be noticed that the great relative length of the frontal lobe is entirely due to this dwarfing of the occipital, for the proportion of the frontal to the parietal is no greater in the gorilla than in the others; and the highest type is to be sought rather in the co-ordinate development of all the lobes and not in the predominance of any one; so that regarded by this standard the gorilla's brain shows one marked feature of inferiority.

It should be remarked that Dr. Pansch, whose judgment must carry great weight, is disposed to regard the divergences from the chimpanzee as sufficient to establish a distinct type of brain in the gorilla.

In the comparisons above instituted, the brain of the bushwoman so carefully and elaborately described by Mr. Marshall in the *Philosophical Transactions* for 1864, that of the chimpanzee described with photographs by the same author in the *Natural History Review* for 1861, and that of the orang in the same journal by Prof. Rolleston have been taken as standards, supplemented by reference to the specimens in the Hunterian Museum.

G. D. THANE

MUSEUM SPECIMENS FOR TEACHING PURPOSES[1]

IT is now generally admitted that a thorough and practically useful knowledge of the form and other properties of natural bodies can only be acquired by an examination of such bodies themselves. The difference between knowing a thing by description only and knowing it from personal acquaintance need scarcely be insisted on.

All teaching, therefore, of the physical properties, especially the form, texture, colour, and relation to one another of the component parts of any natural object, whether organised or inorganic, should be illustrated by reference to the object itself. The more completely the student is enabled to examine it, the more thorough will his knowledge of it be.

In the Department of Biology, which is that to which my remarks must now be limited, very much valuable and practical teaching can certainly be given without the possession of a museum or a single permanent preparation. The commoner and easily accessible animals and plants furnish materials for study and demonstration, which, when done with, can be thrown away and replaced as occasion requires. But it is often desirable to preserve specimens for a considerable time or permanently, either on account of their intrinsic rarity, causing difficulties in procuring them when needed, or on account of the labour and skill which may have been expended upon their proper display, and which it is not desirable to have wasted.

Hence the necessity for museums as most important adjuncts in connection with all establishments for teaching biology.

---

[1] Lecture at the Loan Collection of Scientific Apparatus, South Kensington, July 26, 1876, by Prof. W. H. Flower, F.R.S., Conservator of the Museum of the Royal College of Surgeons of England.

It has been suggested to me on this occasion to give a few hints as to the class of objects best adapted for display in such museums, and the best method of preserving them, especially illustrated by the specimens contributed to the Loan Collection, and having been a collector of specimens and a curator of some kind of museum all my life, at all events since I was nine years old, I do not speak without some experience. As the time at my disposal will be limited, I shall say nothing of the preparation and preservation of specimens intended for microscopical investigation and demonstration, as that is a special branch of the subject, on which there are numerous excellent treatises, and which is considered in other lectures of the present course. I shall therefore confine myself to objects visible to the unassisted eye, and mainly to those derived from the animal kingdom, as having come most fully within the scope of my own experience.

Whether it has arisen from a mistaken impression that museum specimens are scarcely legitimate objects for this exhibition, or whether from the too general neglect on the part of those in charge of collections, of expenditure of labour, ingenuity, skill, and taste, in effecting improvements in arranging, displaying, and preserving the objects under their care, this department of the Exhibition is, on the whole, not very satisfactorily represented, and, compared with some others, puts in rather an insignificant appearance. And yet properly preserved and displayed specimens are essentially "scientific apparatus;" the preparing of such specimens is a most valuable aid to the cultivation of biology, and it is to be regretted that such an opportunity as that now presented of comparing the merits of different processes and of different materials used in the art, has not been more fully taken advantage of.

In considering the subject of museum specimens, it will be convenient to treat, first, of the methods of preservation in a dry state, afterwards of the methods of preserving animals or parts of animals in some kind of fluid, and lastly, to speak of the reproduction, by means of casts and models, of such objects as cannot be conveniently preserved in other ways.

The first method is applicable only to certain parts or tissues of the animal body; either those like the bones of vertebrates, shells of molluscs, chitinous integuments of articulata, &c., which are in their natural condition so hard and dry, that they undergo no material change when completely deprived of all the water contained in their substance, or those like skins, hollow viscera, &c., which may be kept in shape until they are dry by filling them with some stuffing material, or distending them with air. Attempts have frequently been made to preserve soft and fleshy tissues, as the muscles, in a dry state, but by all the processes hitherto adopted they eventually lose so much of their form and substance as to be of little value as representations of actual and natural objects. Such parts of the body, and the whole of the soft-bodied invertebrates, can only be successfully preserved in a fluid medium.

The best known and most generally practised method of preservation in a dry state is that intended to give an exact idea of the whole animal when living, by means of its skin, and the various tegumentary appendages, as fur, feathers, scales, horns, &c., attached to it, removed from the body, and then mounted by means of internal supports and paddings, or "stuffed," as it is familiarly called. The art of preserving animals in this manner is called "taxidermy." Although an art of really great importance for the study of natural history, and one essential, in fact, to its proper diffusion among the masses, it is almost unrepresented in the present collection, the only exceptions being among the "Apparatus for Instruction in Physical Science, contributed by the Committee of the Pedagogical Museum of Russia." The examples sent by this committee, though extremely interesting as illustrations of an admirable system of practical school teaching, and quite equal to the average level seen in most public museums, are of no especial merit as works of art, or as showing improvement over the ordinary methods. That this level should be so low is extremely to be regretted; but as long as curators of museums are contented to fill their cases with wretched and repulsive caricatures of mammals and birds, out of all natural proportion, shrunken here and bloated there, and in impossible attitudes, it will be difficult to get it raised. There may be seen occasionally, especially in continental museums and in private collections, where amateurs of artistic taste and good knowledge of natural history have devoted themselves to the subject, examples enough to show that an animal can be converted after death, by a proper application of [illegible] into a real life-like representation of the original, perfect in form, proportions, and attitude, and almost, if not quite as valuable for conveying information on these points as the living creature itself.

The injurious effect of a low standard of perfection in one branch of art upon another is curiously seen in the drawings of birds often introduced into pictures by some of our most accomplished artists. I could point out in the present Royal Academy exhibition several examples of birds introduced into landscapes, and therefore evidently intended to be representations of living and moving creatures, carefully copied from miserable specimens of "stuffing" of the lowest order. The fact is that taxidermy is an art, resembling that of the painter, or rather the sculptor; it requires natural genius as well as great cultivation. One of the obstacles to its improvement seems to be that few people have knowledge enough of the subject to judge of the execution of the taxidermist as they do of the painter or sculptor. And yet to curators of natural history museums this knowledge should be indispensable. But then they must give up the conventional low standard of payment for "bird stuffing" which now prevails. The artist should be able to devote far more time to the manipulation of each subject than at present, and, moreover, be able to compensate himself for the time he must spend in the study of the anatomy of the dead, and of the form, attitudes, and manners of the living. I have often thought that if a Landseer or a Wolf could have devoted himself to taxidermy, what glorious specimens we should have, and how different then would be the effect of a visit to the "bird gallery" of one of our great museums to that which it now produces. How much of nature would then be learned while admiring the art! And why should this not be? Simply because no one, at least no one in charge of a public museum, thinks of paying for a stuffed bird more than some ridiculously inadequate sum. It may be said that our natural history museums have not funds for such a purpose. If so it is of course a subject to be regretted, and ought to be remedied; but it is not exactly the case. A few really good specimens are far better than an infinity of bad ones. Let the same amount of money, judiciously laid out on skill and labour, now expended on a hundred specimens be concentrated on ten, and a far more valuable and instructive museum will be produced. The remaining specimens for completing the series for advanced students of the subject, should be kept as skins in drawers, in which state they are in every respect preferable to badly-stuffed specimens. They can be handled or examined without damage, and they do not mislead or disgust.

Next to the skin, the part of vertebrate animals most commonly preserved is the skeleton, the bones being, in fact, the most imperishable and easily preserved of all the tissues. The facilities, therefore for the study of osteology are very great, and it has especial importance in comparison with that of any other system, inasmuch as large numbers of animals, all in fact of those not at present existing on the earth, can be known to us by little else than the form of their bones.

These remarks, however, only apply to the skeleton in its *ossified* state, when the bone-tissue is so strongly impregnated with salts of lime, as to resemble, in its properties, rather a mineral than an animal substance. Many of the most important problems of anatomy relating to the skeleton, either the adult skeleton of the lower vertebrates, or the developing skeleton of higher forms, can only be worked out on fresh specimens or wet preparations. The ossified bones, which alone constitute what is popularly called the skeleton, can be studied best from dried specimens.

An osteological collection for teaching purposes should contain a certain number of mounted skeletons of the most characteristic types of vertebrate animals; *i.e.*, skeletons with all the bones joined together in their natural relations, and placed in such an attitude as the animal ordinarily assumes when alive.

In this way the student acquires a general idea of the construction of the framework of the body, the proportions and relative positions of the various parts. But in such skeletons much that is important to know is inaccessible to examination. One bone more or less overlies and hides another, and the articular ends, or those parts that come in contact with each other at the joints, are entirely concealed. Although general comparisons of form and proportion can be made with other skeletons, detailed comparisons of bone with bone are impossible. This applies more especially to skeletons articulated upon the plan almost universally adopted until the last few years, in which all the parts are immovably fixed to each other. It is to a large extent obviated by the method I shall refer to presently, but still, for the complete study of osteology, it is very desirable indeed essential, to have at hand separate parts of skeletons, or individual bones, which may be kept in boxes, drawers, cases, or in any way found to be most convenient. Entire skeletons with the bones separated occupy very little space in boxes, and the t characteristic parts may be selected and mounted in the way I shall presently indicate.

Everyone in charge of a biological museum, however small, should be familiar with the mode of preparing skeletons. I only indicate the outlines of the process, for in this, as in every other part of the work of making anatomical preparations, a few practical lessons from a person already an adept, and a little experience and observation will do more than any description. When the principles are known, the details can be carried out with such modifications and improvements for each individual case, as the skill and ingenuity of the operator can suggest. With regard to museum specimens generally, the question is frequently asked how such or such a preparation is made, and an answer is expected in a few words, which will enable the questioner to do the same himself. This is much as if a novice who had never handled a brush were to ask an artist how he had painted his picture and expect that a few simple directions would put him on a level with the master. Preparation-making is an art which can only be acquired by labour and perseverance, superadded to some natural qualifications not possessed in an equal degree by all.

To return to the bones, as in many respects the simplest kind of preparations. There is a popular notion that skeletons are made by putting animals into ant-hills. So I have been told over and over again ever since I was a child. I must, however, say that I have never actually seen, or even heard of a skeleton really made in this way, though ants, doubtless, especially in hot countries, will make short work of the flesh of an animal's body, leaving at least all the larger bones untouched. But we must adopt some safer and more universally applicable method of proceeding. Another common idea is that some "chemical" substance is ep them in for dissolving the soft parts, and I am often asked "What acid do you use for this purpose?" when a little reflection would have shown that the bones would be the first parts to disappear under the influence of such a menstruum. —water—pure water, is the only thing required in preparing nes and skeletons in the great majority of cases, and in the proper use of the water the art of "macerating," as it is called, chiefly consists.

This process is nothing more or less than placing bones in water and leaving them undisturbed until putrefaction of all the flesh and blood remaining on and around them and within the hollows and small cavities of their interior, takes place, and these soft parts entirely lose their form and structure and become converted into liquids and gases mingled with the water or escaped from its surface; so that when the bones are removed and well washed, nothing remains but the comparatively indestructible true osseous tissue, which, when dried, is hard, clean, and without smell.

Maceration consists, then, essentially in the destruction of the soft tissues by putrefaction, and certain circumstances are essential or favourable to the success of the process. In the first place, the water should not be too abundant in proportion to the amount of animal matter to be destroyed. Then it should never be changed or disturbed until the process is completed. The surface should be exposed to the air, and the loss from evaporation supplied from time to time. The temperature should be uniform and elevated. Cold checks the process; freezing arrests it altogether. If the heat is too great the bones are often greasy and discoloured, as when they are prepared by boiling. It is to the fact that the process varies in rapidity according to so many circumstances that the chief practical difficulty, which is to know when it is completed, is due. If the bones are taken out too soon, unless they are returned immediately to the same water, a check takes place in their preparation. To estimate the necessary time is a matter acquired only by practice and ledge of the surrounding circumstances. Much will de- upon the size of the bones, small bones macerating much rapidly than large ones; also upon their condition, if fresh, they macerate far more quickly than if they have been previously dried (as is the case with skeletons sent from abroad in a rough state), or if they have been kept in spirit or any other

When the bones are to be removed, the water must be carefully poured off through a hair seive, and all the solid matter which remains at the bottom of the jar must be carefully searched from any of the smaller bones which might otherwise be lost. They are then removed to clean water, frequently changed for several days, well washed with a brush if necessary, and dried, if possible, in the sun.

The process of maceration is necessarily attended with disagreeable smells. As long as it continues the surface of the water slowly emits gases; but the worst is when the water is stirred up by pouring it off to remove the bones. Hence it should be carried on in the open air, or what is far better, in a building isolated for the purpose, and in which the temperature may be kept uniform. When maceration has to be conducted among dwellings, it is necessary to be very careful not to disturb the vessels, and to put some disinfectant, as chloride of lime, into them the day before the contents are taken out. This will obviate most of the usual disagreeable effects, and if not used in too great a quantity, will not cause any material damage to the bones. But chloride of lime, when used too freely, is a dangerous agent; it destroys the gelatinous portion of the osseous tissue (which of course is not removed in maceration) and leaves the bones white, chalky, and friable. After proper maceration no chemical bleaching is required. Exposure to sunlight or alternate sun and rain for some months is generally good, especially for large solid bones, though this may be carried too far, as the intensely white, cracked, porous and fragile condition of osseous fragments which have been lying long on moors or hill-sides, shows. Bones are not naturally of a pure white colour, but have a delicate yellowish or creamy tint like that of ivory.

Several substitutes for the process of maceration in water are occasionally adopted under special circumstances.

1. Boiling. This process has the advantage of rapidity, but is seldom resorted to except when absolutely necessary (as in the case of the celebrated skeleton of the "Irish giant" in the Hunterian Museum), as the fatty matter in the medullary cavity is melted and pervades the whole osseous tissue, and gene leaves the bones discoloured and greasy, as may be seen in of those that have been cooked for the table.

2. Burying in the ground may be resorted to when there are no conveniences for maceration, but it is even a slower process. The effect upon the bones is the same, but they are nearly always stained brown by the colouring matter in the soil, and the small ones are apt to get lost.

3. It has lately occurred to me, following out a suggestion of Mr. Seymour Haden's in his excellent letters, entitled "Earth to Earth," relating to the best mode of disposing of the dead, to clean bones by burying them in a basket of charcoal, and though the experiments are not quite complete, they promise excellent results, especially as all the disagreeable odour of maceration is entirely obviated, and the process may even be carried on in inhabited rooms without any inconvenience.

(To be continued.)

OUR ASTRONOMICAL COLUMN

A NEW STAR IN CYGNUS.—On November 24, at 5h. 41m. P.M., the director of the Observatory at Athens, Prof. Schmidt, remarked a star of the third magnitude not far from ρ Cygni, which was not visible on November 20, the last clear evening previous. Its position from observations with the refractor was found to be in R.A. 21h. 36m. 50·5s., N.P.D. 47° 40′ 34″ for the beginning of the present year. At midnight its light was more intense than that of η Pegasi, which is rated a third magnitude by Argelander, and very yellow.

Direct intimation of this discovery was given by Prof. Schmidt to M. Leverrier, and the Paris *Bulletin International* of December 6 contains the few particulars concerning this star which the generally unfavourable weather up to that date had permitted to be put upon record. M. Paul Henry estimated it of the fifth magnitude, so that as in the cases of the similar suddenly-visible stars of 1848 and 1866, it would appear to have remained but a very short time at a maximum. He considered the colour "greenish, almost blue" by comparison with Lalande 42,304, not far distant. M. Cornu examined it on December 2 with a spectroscope applied to the great equatorial, though only during a short break; the spectrum was chiefly formed of bright and consequently proceeded probably from a vapour or lescent gas. On the same evening, but under conditions equally unfavourable, M. Cazin made similar observations with a spectroscope on the 9-inch Foucault equatorial, and with the same result. On December 5 M. Cornu succeeded in making several measures, though still much interrupted by clouds; the *Bulletin* states:—"Il a constaté la presence des trois lignes de l'hydrogène, C, F et $\lambda = 434$ (échelle des longueurs d'onde); la raie D, du sodium, la raie b du magnésium et deux autres $\lambda = 535$ et $\lambda = 503$. La première parait coïncider avec la raie 1474 (échelle de Kirchhoff) ou $\lambda = 532$ observée pendant les éclipses dans la couronne solaire; ce qui ferait peut-être penser que la raie notée comme correspondant au sodium pourrait être celle de l'élément solaire appelé hélium."

There is a slight confusion about the declination of this star, which, according to the lithographed *Bulletin*, M. Paul Henry made three minutes less than Prof. Schmidt, while the declination, as reduced by the latter to 1855·0, differs more than a minute from his declination for 1876·0, correctly carried back.

The nearest catalogue star is one 9·2 m. = + 42°, No. 4,184, in the sixth volume of the Bonn Observations, $\Delta\alpha = -24{\cdot}6$s., $\Delta\delta - + 4' 3''$, according to Prof. Schmidt's place. We find no star in the position of the new one, in the *Durchmusterung*, nor in Lalande, d'Agelet, Bode, Bessel, &c., nor Harding's Atlas.

The remarkable star of 1866 (T Coronæ Borealis) descended to the limit of unaided vision in ten days from its discovery by Mr. J. Birmingham, of Millbrook, Tuam, on the night of May 12, when it appears to have become suddenly visible as a star of the second magnitude: it is now a little over the eleventh magnitude in Bessel's scale extended.

The similar object of 1848, detected by Mr. Hind on the morning of April 28, then of the sixth magnitude, and certainly less than the ninth on April 4 and 5, attained its maximum about May 7, and at that time was a little brighter than 20 Ophiuchi, rated a fifth magnitude by Argelander. The maximum brilliancy assigned to this star in Schönfeld's last catalogue is one magnitude too low. It continued visible without the telescope to the end of May. Last summer it was not over the thirteenth magnitude.

[By observations at Mr. Bishop's observatory, Twickenham, on the 12th inst., the position of the new star for 1876·0 is in R.A. 21h. 36m. 50·35s. N.P.D. 47° 43′ 4″; Prof. Schmidt's declination is in error. The star was of the seventh magnitude and colourless; the sky, however, very indifferent.]

THE OPPOSITION OF MARS, 1877.—In addition to the stars observed by Bessel, which are mapped on the Astronomer-Royal's Chart in the *Monthly Notices* of the Royal Astronomical Society, the following lie near the path of the planet at this opposition:—

1. An uncatalogued star of the ninth magnitude, the place of which for 1877·0 is in R.A. 23h. 19m. 55·3s., N.P.D. 101° 21′ 49″; the planet in conjunction with this star, August 25·292, G.M.T. 5′ 14″ north.

2. Lalande, 45504 – 7½ mag.; mean place, 1877·0, in R.A. 23h. 8m. 56·1s., N.P.D. 102° 14′ 0″; the planet in conjunction with this star, September 5·224, 3′ 10″ north.

On September 6·415 Mars will be in conjunction with, and 2′ 15″, north of a tenth magnitude, the mean place of which is in R.A. 23h. 7m. 46·4s., N.P.D. 102° 18′ 6″.

There is every reason to expect that this favourable opposition of Mars will be very completely observed with the view to another determination of the solar parallax.

NOTES

FOR the erection of a monument to Linnæus 36,000 crowns have been received. The monument will be erected in Stockholm, and will be unveiled on January 10, 1878, the hundredth anniversary of the death of the great naturalist.

THE inauguration of the Liebig monument in the new promenade at Darmstadt, will shortly take place. Pupils, friends, and admirers of Liebig are invited to be present on the occasion.

M. DE LESSEPS presented to the Academy of Sciences at its last sitting, the final report of Capt. Roudaire, who has returned from Tunis after having completed his survey of the Algero-Tunisian depression. The project is now quite complete and ready for execution. All the trigonometrical measurements have been taken, and the preliminary steps for making an inland sea have been considered. A commission, of which M. de Lesseps is a member, and will most probably be the referee, was appointed by the President, Admiral Paris. The opposition offered by some influential members of the Academy is now considered as being quite at an end.

FROM the *Tour du Monde* we learn that an American company proposes to introduce fur seals from Alaska into Lake Superior. The temperature of the lake is considered to be sufficiently cold for the purpose, and the company hopes to obtain from Congress and the Canadian Parliament an Act protecting the creatures from slaughter for twenty years, after which time it is supposed that they will be sufficiently acclimatised and numerous to form subjects of sport.

NEWS has been received from Gen. Nansauty, the adventurous observer who has located himself near the top of the Pic du Midi for the purpose of taking meteorological observations during the winter. He and his companions have been made comfortable and secure, the only thing wanting being a telegraph to connect the Pic du Midi with Toulouse as Puy-de-Dôme has been with Clermont. This will very likely be the work of next year. Up to the end of last week the weather was very mild and almost no snow had been observed.

AT the Arctic meeting of the Geographical Society on Tuesday night, honoured by the presence of the Prince of Wales, Sir George Nares and the other officers of the Expedition met with a deservedly enthusiastic reception. Addresses were given by Sir George Nares and Captains Stephenson and Markham, in which details were given of the work of the Expedition. Sir G. Nares gave a clear account of the currents of the Atlantic and Pacific in their bearing on the condition of the ice in the Arctic regions. We may now consider the Polar basin, he stated, as a locked-up bay continuing out of the narrowed North Atlantic Channel, with a warm stream of water constantly pouring into it between Spitzbergen and Norway, and a cold icy one as constantly running out between Spitzbergen and Greenland, and also through the very narrow straits between Greenland and America; the first conveying an enormous source of heat towards the north, the latter causing the intense cold of Canada and that on the east coast of Greenland and North America. In the Polar Sea, near the inflow of the warm water, we should naturally expect to meet the lightest ice and an early season; near the outlets the heaviest ice. And such is found to be the case. Heavy ice has been traced all the way from Behring Straits eastward to Bank's Land, and from there, west of Prince Patrick Island, to Ireland's Eye, from which point it is lost; for the sledging parties under Admirals Richards and Osborn, journeying along the north shores of the Parry Islands, found light ice. It is therefore concluded with certainty that some protecting land exists to the northward. From the *Alert's* winter quarters the heavy Polar ice was traced by Aldrich for one-third of the distance towards Ireland's Eye, leaving 400 miles still unknown; to the eastward, Beaumont proved that it extends for 100 miles, leaving about 500 miles still unexplored between his farthest and the farthest of the Greenland Arctic Expedition under Koldewey. We have now a distinct knowledge of the nature of the ice in the Polar Sea. Whether that sea extends to the Pole or across the Pole, we cannot, according to Sir George Nares, be absolutely certain, but by reasoning, we may safely predict that a very broad opening exists north of Cape Columbia, and Sir G. Nares firmly believes that it extends at least as far as the Pole. During winter there appears to be a compact mass of ice in the Polar the thinner portions of which are melted by summer heat, leaving open lanes or pools of water, giving sufficient scope for the broken-up permanent ice-mass to drive backwards and forwards according to the wind or current, its main course being towards the channels of outlet, by which a small portion escapes. By the end of September the increasing frost cements together the struggling masses, and young ice forms on the open spaces to about seven feet thick. Thus the pack covering the Polar Sea is a collection of separate pieces of ice, movable among each other during the summer like the pebbles and boulders in a river bed, each piece grinding against its neighbour as the whole body jostles its way along, slowly pressing forwards towards the outlet between Spitzbergen and Greenland. Sir George Nares showed that by calculation an extremely small proportion of the Polar ice can escape by the various channels, and that much of what remains may easily be at least 100 years old. Many other valuable observations were made on Polar questions by Sir George, and Captains Stephenson and Markham read interesting papers on "Arctic Winter Experiences" and "Sledge Travelling."

Dr. Petermann has sent us a long letter on the English Arctic Expedition, which he has addressed to the *President of the* Geographical Society. Dr. Petermann says he has made himself acquainted with the history of every Arctic and Antarctic expedition that has ever been undertaken, and it appears to him "there never was a more able and heroic expedition than that of Capt. Nares. Capt. Nares's expedition may be said to have '[illegible],' as it were, a great portion, say one-third, of the Arctic From Smith Sound to Behring Strait, the of the Palæocrystic Sea, our knowledge is entirely due to British enterprise and perseverance." Petermann thinks Sir George Nares has exploded the fallacy of the continuous navigability of the Smith Sound route, and that it required the greatest moral courage to return with results diametrically opposed to what was expected. He thinks that had he been able to stay another winter and gone round to East Greenland, he would also have "finished" the Pole. Petermann thinks it has been a triumph of seamanship that the commander has been able to bring back the two ships safe and sound, and that if our "enlightened and liberal Government remains true to the English way of doing things, in a complete way, and not by half-measures, it is to be hoped that these vessels will once more be sent out by a more promising route." He then refers to the six routes to the pole, advocating the Novaya Zemlya and the East Greenland routes. He believes there is a great open sea all along Northern Siberia, and states that Prof. Nordenskjöld intends in 1878 to sail right across from Norway to Behring Strait. Petermann believes that a high latitude could easily be obtained along the west coast of Franz-Josef Land, and maintains that no proper attempt has been made since Parry's journey in 1827 to push north beyond Spitzbergen. But of all the routes that by East Greenland is the one which he advocates most strongly. He maintains that throughout the summer the East Greenland coast is almost free of ice, and even in winter there is a strong outward drift. He firmly believes that an ex[illegible], like that which has just returned, would have no difficulty in sailing direct north, crossing the pole, and coming out at These views are based on the observations of ; captain, David Gray, and on the known drift of the The well-established current by the Smith route brings down much ice, but much more of the ice must escape by the wide opening between East Greenland and Spitzbergen. The ice-drift must leave an open space behind, and there is therefore good reason to believe that in the Polar region will be found an open sea. Petermann is convinced that Sir G. Nares, with the *Alert* and *Discovery*, could steam right to the pole by this route, probably in one season. He thinks it possible, moreover, that East Greenland and Franz-Josef Land may approach each other towards the pole, and still maintains the prolongation of Greenland across to Behring Strait, in, however, it appears to us, a somewhat modified and less objectionable form. He considers the central region to be divided into two nearly equal areas of land or islands, the one extending from the shore of East Greenland in about 20° W. long. over Baffin's Bay, Parry Island, and Point Burrow, Behring Strait, and Cape Yakan, in about 176° E. long.; the other half thence all along the Siberian Coast, over Franz-Josef Land, Spitzbergen, to East Greenland. These two regions are in all respects distinct. In the two former, or western, the land prevails, in the latter, sea. "It is not at all unlikely," Petermann states, "that Eskimos will yet be found right under the North Pole." A Swedish and a Dutch expedition have, he assures us, been decided on. He has no hope of anything being done, meantime, to carry out Weyprecht's scheme. The mass of data collected by various expeditions has not yet been half worked out. He still maintains: "It might be done, and England ought to do it." We have endeavoured to give the drift of Dr. Petermann's letter, without comment.

Dr. Petermann has sent us Nos. 123–5, of his valuable series of papers, "Geographie und Erforschung der Polar Regionen." In these he discusses the results of Nordenskjöld's recent expedition, of the Siberian expedition of Finsch, Brehm, and Ziel, and those of the English expedition. As prefatory to an abstract of Nares's report, he describes and discusses some of the observations of previous expeditions, all tending to show the impracticability of the Smith Sound route, and the probability of an open Polar Sea. The papers are accompanied by three maps illustrating the observations and theories referred to, and whatever may be thought of the latter, are a valuable contribution to the polar question.

M. W. de Fonvielle writes to us protesting against any scheme of Arctic exploration by means of balloons in the present state of the aeronautical art. No such scheme is practicable without some certain means of directing a balloon and insuring its progress in any direction independently of air-currents; and as no method of steering and propulsion has yet been invented that merits consideration, discussion of the subject on existing bases is totally unscientific.

The German Arctic Exploration Society has received a telegram from the Ob Expedition dated Jenisseisk, the 5th instant, announcing that Captain Wiggins has found a good harbour in the Podarala Bay, where he remained several weeks; he also discovered a large island north of the mouth of the Ob, and a new land route to the Jenissei. He found the water way up the Jenissei to Nurjaha good.

About two years ago the Registrar-General discontinued the practice of sending, free of charge, to the London Medical Officers of Health, copies of the returns of deaths made by the local registrars. Among the three vestries that still protest against this change for what is public property, is that of St. George's, Hanover Square. For the last two years, therefore, the Medical Officer of Health for St. George's, Dr. Corfield, been without the e returns for his district, [illegible] in his fourth annual report, just issued. It the year, according to the Registrar-General's returns, out ninety-three deaths from six to the sanitary inspector. "We states, "of seven deaths occurred, or what precautions he spread of the diseases by means of infected bedding, clothing, &c. This shows, I think, quite clearly, that it is necessary that in some way or another I should be supplied with the mortality returns, and especially with details of the deaths from infectious diseases. As regards the cases which do not prove fatal, there s at present no official way of obtaining information about them." Dr. Corfield has stated so clearly the ill effects of the present arrangement as to show that there is evidently urgent need for an alteration.

At the Hamburg meeting of the German Naturalists, Prof. Virchow gave an address on the present position of anthropology. In introducing his subject he pointed out that anthropology, although one of the youngest of the sciences, already occupies as advanced a position as many of the older branches of study; and also that the races possessed of least ability are also those lowest in the scale of culture. To judge of the capacity for culture from the signs of it which exist is only admissible in the case of people who are surrounded by great intellectual activity, but not in the case of entirely isolated people. Thus the Australian Papuas by no means stand so low as has hitherto been believed. On this fact Virchow founds an important doctrine, which opposes the idea that such people must necessarily fade away when they come into contact with civilisation. Virchow thinks that the extinction of such races is rather to be ascribed to the barbarousness of Europeans and to the incapacity of the latter to educate the former. There is yet no evidence that uncivilised races must become extinct, which indeed is contradicted by the history of Europeans themselves. If the civilised people of the present day be considered as the product of a higher development, we cannot regard the possibility of such a development as a cause of the extinction of such people as are now on the same platform of culture which we ourselves once occupied. In relation to this Virchow spoke of the value of a systematic observation, of collections of skulls weapons, clothing, also of evidences of intellectual activity, religious ideas, language, &c., and urged the important services that might be rendered in this respect by captains both in the navy and in the merchant service. No time is to be lost; every day is of value, since many of the lower races are rapidly becoming extinct. Virchow showed the utility of such observations by reference to the German peoples, of whose anthropology we as yet know almost nothing. Osteological remains, to be of any scientific value, should be seen in the place where they are found. Virchow spoke of the value of the statistics recently taken as to the colour of the hair, eyes, and skin of German children, to which we have already referred.

The Siberian explorers, Brehm and Finsch, have arrived at St. Petersburg, after a most successful journey.

The following extracts of a letter from Dr. Miklucho Maclay, dated July 3, Maclay Coast (New Guinea), appear in the *Golos*, November 28:—"I landed on June 28; the natives received me in a very friendly way, and were not at all astonished to see me amongst them again; they said they had been long awaiting my arrival, as I had said when leaving them I would soon return. Since the departure of the *Isumrud* in December, 1872, no ship had visited the shore. Three or four months after that time there was an earthquake on the island, which destroyed many villages in the highlands. Talking with my old acquaintances, I was astonished to hear how many Russian words they had rotained since my first stay; they pronounce the words perfectly, and have introduced them in common use. Hundreds of natives from the neighbouring settlements helped in building me a house. I have brought for the Papuas various seeds of useful plants and of fruit-trees, and I hope they will grow as well as the Indian corn I left here in 1872. I expect soon to make some excursions in the highlands." The captain of the *Sea Bird*, who transmitted this letter, adds that Dr. Maclay was perfectly well on board the ship during the cruise and on his landing.

The Omsk correspondent of the Irkutsk newspaper *Siberia*, writes under date September 27, that M. Potanin's expedition in Mongolia (Nature, vol. xiv., p. 534) has been stopped by the Chinese authorities at Toolty, a short way beyond the Chinese frontier. Arriving at Toolty, the members of the expedition expressed their wish to make a visit to the Governor of the place. Being told that he resided in a convent some miles from the town, they proceeded thither, but on their arrival they were informed that the Governor was not at home, and that the visit must be made next morning. On going next morning to the convent they were met at the doors by a hostile crowd, which soon began to throw stones at them, seriously injuring two persons. The authorities then appeared and took the members of the expedition into custody, but released them next day, announcing that they could not answer for their safety if they insisted on proceeding further.

Some very important geological discoveries have been made by Prof. Hartt and his assistants in Brazil. Working over again the region explored by Prof. Theodore B. Comstock in 1870, and by Messrs. Hartt and Derby in 1871, they have extended the Devonian down 1,000 feet below the beds discovered by Messrs. Smith and Comstock. The lower beds are Oriskany, with the characteristic North American fossils, as well as some others (seventy-five species in all) which have undoubted Devonian affinities. Carboniferous beds were also discovered to the northward, making a complete section from the base of the Devonian to recent beds in the lower Amazonian Valley.

Prof. Tyndall has accepted the office of President of the Midland Institute for 1877.

The professors of the new School of Anthropology established in Paris under the patronage of the Faculty of Medicine and the Municipal Council, intend to organise excursions. The first of these was made last Sunday to the St. Germains Museum of National Antiquities, of which M. Mortillet is the sub-director. He explained to a large number of visitors the arrangement of the collections and the scientific value attached to the several curiosities which are exhibited.

M. Leverrier has organised meteorological warnings for St. Cloud, Clichy, Boulogne, and Levallais Perret, and will gradually extend them to the suburban districts. He will give a lecture at Boulogne to the several delegates of Communes for the purpose of teaching them the use of the meteorological maps published daily by the Observatory.

On the 16th of next month, at the scientific meeting of the Zoological Society, we are informed that Captain Feilden, Naturalist to the Arctic Expedition, will exhibit the birds obtained by him in the regions he has so recently traversed.

At the last meeting of the French Geographical Society, it was intimated that M. Jules Trebeau had been sent to explore French Guiana, which although a part of the territory of a civilised nation is almost untrodden by explorers. M. Trebeau will proceed by the river Maroni, up to its source, with a party of three French and ten negroes, and will return by the Oyapok or Amazon, according to circumstances.

"Niphon and its Antiquities" is the title of a pamphlet by Mr. W. C. Borlase, in which from personal investigation during a stay of some weeks in Japan, and the study of the best works on the subject, the author gives an interesting summary of what is known of the ethnology, mythology, and religions of the Japanese. The pamphlet is published by Brendon and Son, Plymouth.

IN a paper in the *Cleveland* (U.S.) *Herald*, November 14, entitled "Archæological Frauds," Col. Whittlesey examines some of the recent so-called prehistoric finds in some parts of the United States, and comes to the conclusion that most of them are extremely suspicious; among these is the well-known Grave Creek inscription.

THE New York Aquarium, some account of which we gave recently, is publishing a fortnightly journal. Of course it is essentially popular, but, while keeping an eye to the success of the aquarium, it gives considerable information concerning its inhabitants.

WE have received from New South Wales several papers which show that there is a creditable amount of activity in connection with science in that colony. We recently published a brief account of two meetings of the Royal Society of the colony, and from the rules, list of members, and other documents in connection with that body, which have been sent us, we have hopes that it will become an important centre of scientific influence and culture. We believe that the recent development of the Society is greatly due to the energy of the hon. secretary, Prof. Liversidge. "New South Wales; its Progress and Resources," is the title of a paper prepared by the authority of the Commissioners for the Philadelphia Exhibition, and giving, in brief space, an interesting account of the rapid progress of the colony. Along with this is a mineral map of New South Wales, showing the localities of the principal minerals, the back being utilised for the tabulation of some important statistics. As text to this map is a long and valuable paper by Prof. Liversidge giving a complete account of the minerals of the colony. Finally, we have by the same gentleman, a "Report of the Sugar-Cane Disease in the May River District, Queensland."

WE noticed some time ago the opening of Mr. Rooke Pennington's local museum at Castleton, in Derbyshire. We are informed that the result has been a great impetus to scientific study in that and the neighbouring Peak villages, and that a course of lectures has been arranged in connection with the museum. The first lecture will be delivered by Mr. Ralph Betley, F.G.S., who will take as a subject "Water." Mr. C. E. De Rance will give the second.

A VERY valuable and interesting collection of silver ores from Chili and Bolivia was sold by auction the other day by Mr. Stevens at his sale rooms in King Street, Covent Garden. Some of the specimens realised very high prices, one piece of red silver about the size of an orange being bought by Mr. H. Ludlam for 200*l.*, another about a quarter the size, with very perfect crystals, was secured by Mr. Bryce M. Wright, the mineralogist, for 100 guineas, and the remainder, comprising about 100 small specimens, were sold at proportionate prices; we believe Mr. Wright bought nearly a third of the collection, which was probably one of the finest ever brought to England.

THIS year Dr. Hermann Müller was accompanied to the Alps by one of his pupils, Ed. Gaffron, who collected, prepared, and carefully mounted fine specimens of all those Alpine flowers which Dr. Müller has observed and described, or will describe, in NATURE, in his articles on the Fertilisation of Flowers by Insects. Twenty complete collections have been made, and the young collector is anxious to sell them in order to raise funds to accompany Dr. Müller next summer. No doubt a number of our readers will desire to possess such a collection, which may be obtained by writing to Eduard Gaffron, Realschule, Lippstadt. The price, we believe, of a single collection is fifteen shillings.

THE additions to the Zoological Society's Gardens during the past week include a Patas Monkey (*Cercopithecus ruber*) from West Africa, presented by Mr. J. W. Feather; an Australian Crane (*Grus australasiana*) from Australia, presented by Mr. H. Roberts; two Crested Guinea Fowls (*Numida cristata*) from West Africa, presented by Mr. Daniel R. Ratcliff; two King Parrakeets (*Aprosmictus scapulatus*) from New South Wales, presented by Miss E. Rigby; a Short-eared Owl (*Otus brachyotus*), European, presented by Mr. W. R. Stanley; a Snowy Owl (*Nyctea nivea*), European, presented by Mr. John Kendall; a Brown Capuchin (*Cebus fatuellus*) from South-east Brazil; a Kinkajou (*Cercoleptes caudivolvulus*) from South America, a Royal Python (*Python regius*), a West African Python (*Python sebæ*) from West Africa, deposited.

SOCIETIES AND ACADEMIES

LONDON

Linnean Society, December 7.—Mr. G. Bentham, vice-president, in the chair.—Mr. Francis Day read Part I. of the "Geographical Distribution of the Fresh-water Fishes of India." This contribution aims towards solving the vexed question of whether the fauna of Hindostan is mostly African or Malayan. The author first separates the true fresh-water species from those which enter rivers from the sea for breeding or predacious purposes. Out of nine families of Spiny-rayed fish (Acanthopterygians), only two are likewise found in the African region, but one of these is in Madagascar, which is doubtfully African; the other is also found in the Malay Archipelago, which possesses representatives of eight out of nine families. Each of the forty-five known species is then followed out, and the author considers that the Indian and Malayan fauna (of the group in question) are essentially identical, whereas the species are scarcely represented in Africa. The fresh-water fishes of Ceylon, the Andamans and Nicobars, he believes, are also strictly Indian, whilst as these fishes cannot be spread except by line of fresh-water communication, it thus appears highly probable that these islands were at one period connected to the continent of India. Moreover, certain forms exist in Malabar which are absent from the rest of India, but reappear in the regions of Chittagong or Siam.—Mr. J. G. Baker gave the substance of an exhaustive memoir on a general systematic arrangement of the Iridaceæ (the Iris family). Nearly all the Iridaceæ inhabit temperate regions, and may be grown successfully in the open air in this country. Some are among our most familiar garden genera—for instance, the Crocus, the Iris, and the Gladiolius. Altogether about 700 species and sixty-five genera are now recognised. In his present classification the structure of the perianth mainly guides the author to adopt three primary divisions—(1) Ixieæ, (2) Irideæ, and (3) Gladioleæ, the above common garden plants serving respectively as typical examples of these groups. The three divisions in question are again subdivided into—(*a*) Those having *bulbs with free stamens*; (*b*) Those having *bulbs with monadelphous stamens*; (*c*) Those *wanting bulbs, but with free stamens*: (*d*) Those also *devoid of bulbs with monadelphous stamens*. As regards distribution, 312 genera are found at the Cape; in Europe and North Africa, 94; Temperate Asia, 89; Tropical America, 82; Tropical Africa, 56; South America, 34; Australia, 31; and Polynesia, 1.—The Rev. W. A. Leighton communicated a description of eleven new British Lichens, seven of these belonging to the genus *Lecidea*, one to *Odontotrema*, and three to *Verrucaria*.—The Chairman passed some remarks on a folio treatise concerning the structure and culture of the quinine-bearing trees (*Cinchona*) in our East Indian Plantations, by I. E. Howard, F.R.S.—Mr. T. Christy exhibited specimens of the so-called Black Coral (*Antipathes*) from the Philippines, referring to its commercial value.—Thirteen gentlemen were elected Fellows of the Society.

Zoological Society, December 5.—Dr. E. Hamilton, vice president, in the chair.—A letter was read from Count T. Salvadori, announcing that a new species of Paradise-bird, of the genus *Drepanornis*, had been discovered near the most inland point of Geelvink Bay, New Guinea.—A communication was read from Mr. Andrew Anderson, containing some corrections of and additions to previous papers on the Raptorial Birds of North Western India.—Mr. Francis Day read a paper on the fishes collected by the Yarkand Mission, in 1873, to which the late Dr. Stoliczka was attached as naturalist. The paper gave an outline sketch of the fresh-water fishes of Hindustan, Afghanistan, Western Turkestan, Yarkand, Tibet, and Cashmere. The author showed that the principal fishes of Yarkand belong to a local group of carps, termed "Hill Barbels, or *Schizothoracinæ*," by McClelland: that this group is almost restricted to cold and elevated regions, spreading to the most eastern portion of Western Turkestan, Afghanistan, and along the western slopes of the Himalayas to China; and that these forms are entirely distinct from the carps of the plains to the south of the Himalayas.—A communication was read from Mr. Martin Jacoby giving the descriptions of new genera and species of Phytophagous Coleoptera.—A communication was read from Dr. A. Günther, F.R.S., containing the description of a new species of lizard from Asia Minor, which he proposed to name *Zootoca danfordi* after Mr. C. G. Danford, its discoverer.—Dr. Günther communicated a paper by Mr. W. Ferguson, of Colombo, containing the description of a new species of snake of the genus *Aspidura* from Ceylon, for which the name of *A. guentheri* was proposed.

Geological Society, November 22.—Prof. P. Martin Duncan, F.R.S., president, in the chair.—The following communications were read:—On the pre-Cambrian (or Dimetian) rocks of St. David's, by Henry Hicks, F.G.S. Referring to the ridge of pre-Cambrian rocks, which he described in a former paper as running down the St. David's promontory, and as previously supposed to consist of intrusive syenite and felstone, the author stated that he had now found it to be composed exclusively of altered sedimentary rocks of earlier date than the Cambrian deposits, the conglomerates at the base of which are chiefly made up of pebbles derived from these rocks. Recent investigations had led him to the conclusion that the main ridge was composed of two distinct and decidedly unconformable formations, the older of which, composed of quartzites and altered shales and limestones, constituting the centre of the ridge, has a north-west and south-east strike, and dips at a very high angle; whilst the newer series, consisting of altered shales, and having at its base a conglomerate composed of pebbles of the older rock, has a strike nearly at right angles to that of the latter. For the former he proposed the name of Dimetian, and for the latter that of Pebidian. The author indicated the points of resemblance between these pre-Cambrian rocks and the Laurentian of Canada, the Malvern rocks, and others in Scotland and elsewhere, but thought it safer at present to abstain from attempting any definite correlation of them. The exposure of the older, or Dimetian series, led the author to ascribe to those rocks a thickness of at least 15,000 feet; the upper, or Pebidian rocks, which flank both sides of the old ridge through a great portion of its length, are apparently of considerably less thickness, but they are in most parts more or less concealed by Cambrian deposits overlying them unconformably. Running nearly parallel with Ramsey Sound is another large mass of the author's Pebidian rocks, and at the south-western extremity of Ramsay Island they compose a bold hill almost 400 feet high, and on the east side of this a fault, with a downthrow of at least 14,000 feet, has brought the Arenig beds into contact with the pre-Cambrian rocks.—On the fossil vertebrates of Spain, by Prof. Salvador Calderon, communicated by the President.

Anthropological Institute, November 28.—Col. A. Lane Fox, F.R.S., president, in the chair—An Indian hammock from the city of Mexico, weapons from Perak and British Guiana and a Bosjesman's skull were exhibited.—The President, by permission of Messrs. Bollin and Feuardent, exhibited some terra cotta figures from Tanagra, Bœotia, and read some notes thereon. Mr. Hyde Clarke and others joined in the discussion.—Papers on the Lapplanders, by A. von Humboldt von Horck, and on the tribes of British Guiana, by the Rev. D. Harper, were also read.

Royal Microscopical Society, December 6.—H. C. Sorby, F.R.S., president, in the chair.—The President exhibited a *facsimile* of Jancen's microscope, made by permission of the Dutch Government from the original, exhibited at the South Kensington Loan Collection.—A paper by the Rev. W. H. Dallinger was read by the Secretary, on *Navicula crassinervis*, *N. rhomboides* and *Frustulia saxonica*, as test objects, in which, after referring at some length to the recent discussion upon the subject of their identity or difference, he expressed his belief that they were all specimens of *Rhomboides*, differing only as to size; and in support of his opinion, a number of very beautifully executed drawings were exhibited to the meeting, showing the microscopical appearance of the diatoms in question under a magnifying power of 800 diameters.

Institution of Civil Engineers, November 28.—Mr. George Robert Stephenson, president, in the chair.—The paper read was on the chalk water system, by Mr. J. Lucas.

CAMBRIDGE

Philosophical Society, November 20.—Mr. O. Fisher read a communication on the effect of convective currents on the distribution of heat in a bore-hole. This paper was supplementary to one read by the author on November 29, 1875. The temperatures obtained in the boring at Speremberg, near Berlin, which attained a depth of upwards of 4,000 feet, were reduced to a mean law by Prof. Mohr, of Bonn, and had been already shown by the author to conform closely to those expressed by a parabolic curve, having its axis horizontal, and its vertex at a depth of 5,171 feet expressed by the equation—

$$v = -\frac{251}{10^8}x^2 + 0{\cdot}012982\,x + 7{\cdot}1817,$$

v being the temperature expressed in Reaumur's scale, and x the depth. An elaborate account of the observations taken in the Speremberg boring has been given by Dunker in a paper entitled "Ueber die Benutzung tiefer Bohrlöcher zur Ermittelung der Temperatur des Erdkörpers, und die desshalb in dem Bohrloche zu Speremberg auf Steinsalz angestellten Beobachtungen." The temperature curve within the earth's crust being believed to be a straight line expressing an increase of 1° Fahr. for 60 feet of descent, it was shown that the departure from this law in a large bore-hole (in the present case a foot in diameter) might be accounted for by vertical currents. At the surface of the water its temperature, from radiation and evaporation, will nearly coincide with that of the upper bed of rock. As we descend, the tendency will be for the currents to warm the water in the upper part of the bore-hole above the normal temperature of the rock, and to cool it in the lower part below the temperature of the rock. At a certain depth the temperatures of the water and rock would be the same. By Dunker's table this appears to have occurred at the depth of about 200 feet. A diagram representing graphically the effects mentioned will appear, accompanied by the proper explanations, in the forthcoming number of the Society's *Proceedings*.—Prof. Hughes then gave a criticism of the evidence for pre-glacial man, which we have already noted.

MANCHESTER

Literary and Philosophical Society, October 31.—Rev. William Gaskell, M.A., in the chair.—Remarks on the general affections of the barometer noticed by Mr. J. A. Broun, by Prof. B. Stewart, LL.D., F.R.S. Mr. J. A. Broun has found as an experimental fact that simultaneous variations of the barometric pressure occur at such distant portions of the globe as to lead to the inference that the whole globe is thus affected, from which Mr. Broun infers that some other force besides gravity is concerned in these phenomena. We know as a matter of fact that there are causes at work which give rise to electrical separation, although we may not know the precise nature of these causes. Thus evaporation goes on from the surface of the sea and of the land. Changes take place in the amount of aqueous vapour held by the air, and also probably in the molecular state of this aqueous vapour. But although we may not be able to point to the specific actions which produce electrical separation, we know that such separation implies a one-sidedness or heterogeneity; and since gravity will presumably act differently on the two things, we may probably suppose that one of the constituents which have caused this electrical separation may have a tendency to mount upwards in the atmosphere, while the other may have a tendency to move downwards. For instance, if evaporation from the surface of the earth or sea be one cause of this electrical separation, we might imagine the land or sea to become electrified in one way, while the vapour electrified in the other direction might mount in the air, owing to its being specifically lighter. In fine, whatever be the cause of the electrical separation, we may presumably suppose that the one constituent will either remain below or find its way downwards, while the other, carrying with it its peculiar electricity, will mount upwards. Now, may not the earth be regarded as a Leyden jar, the sea and earth forming one coating, and the upper, rarer, and hence electrically conducting strata of air forming the other coating; and will not the tendency of the action above named be to charge the upper coating with one kind of electricity and the under with another? Such a process would, of course, be continually going on, while on the other hand the earth, regarded as a Leyden jar, would, by means of thunderstorms, and possibly by other means, be continually discharging itself. Next, let us suppose that by some extensive local circumstances a greater than usual electrical separation and charging of the earth jar has been going on. The effect of this local cause would, however, not be local, but would contribute to increase the charge of the earth as a whole—as one jar in fact, so that the earth as a whole might, for a short period, be increasing its charge—the local charging causes being in excess of the local discharges. Next, would not this excessive charge appear to increase the barometric pressure of the air over the whole earth? On the other hand we may imagine the discharging influences to be sometimes in excess of the charging causes, and then the electrical separation of the earth jar would diminish, and the barometric pressure of the air appear to diminish also. These remarks are put forward not as a formal theory, but rather with the view of inviting discussion. In considering a fact such as that brought forward by Mr. Broun, we must first endeavour to explain it by the operation of some known cause. I have therefore introduced a force which we know to exist, and a mode of operation which is not at first sight improbable. It may be thought that electrical separation can hardly be great enough to produce a sensible barometrical difference. Let this be proved, and a point will be gained by the dismissal of what seems at first sight a possible hypothesis. Meanwhile—to bring these remarks to a practical issue—might it not be well to examine the records of atmospherical electricity corresponding to the dates of Mr. Broun's observations with the view of ascertaining whether Mr. Broun's results are in any way connected with the electrical state of the earth's envelopes?

GENEVA

Physical and Natural History Society, October 5.—Prof. Plantamour communicated to the Society the continuation of his investigations into the climate of Geneva, dealing especially with winds, cloudiness, and rain. As to winds, he has obtained for the last fifteen years a confirmation of the previous results, viz., that the local winds at Geneva play an important part in consequence of the action of the lake; the land breeze at the lake giving a south wind, prevails in the warm season, especially during the morning and evening hours. Generally the south wind prevails from April to October, while the *bise*, or north wind, prevails from November to March. With regard to cloudiness, M. Plantamour has established that the daily variation changes in a notable manner with the season. In winter the minimum of nebulosity occurs at 4 P.M., while in summer it is the afternoon hours that are most overcast. In winter it is the night cold which is the principal cause of clouds; in summer the afternoon heat. December is the most cloudy month; July and August are the clearest months, with difference from one year to another. Examining next the period of fifty years from 1826 to 1875, in reference to the quantity of rainfall, M. Plantamour arranges the years into very dry, dry, wet, and very wet, according to the proportion of rain which they have given, as compared with the mean. It follows from this classification that years of different qualities succeed each other in an order entirely irregular; that a year may be followed as likely by a similar as by a different or very different year in point of humidity. However, there are series of years in which the rainy prevail, and others in which the dry prevail. Thus, from 1826 to 1837 there were eight dry years and four wet; from 1838 to 1856, fourteen wet years and five dry years; from 1857 to 1865, six dry years and three wet. Still there is no regularity, no periodicity in the return of these dry and wet epochs, nothing especially which we may connect with the eleven-year period of sun-spots.

PARIS

Academy of Sciences, December 4.—Vice-Admiral Paris in the chair.—The following papers were read:—On a note of P. Secchi relative to the formation of hail, by M. Faye. He is surprised at P. Secchi giving out as new the idea of trombes with vertical axes bringing down cold air from the upper regions. He urges the sun-spot analogy.—Indices of a new genus of edentate mammifers, fossil in the Saint Ouen Eocene deposits, by M. Gervais. The peculiarities of some of the fragments (chiefly a calcaneum, and metatarsal or metacarpal bones) are described. The animal seems to have been like *Macrotherium* and *Ancylotherium* in some respects, unlike in others. M. Gervais names the genus *Pernatherium*, and the species *P. rugosum*, in allusion to the wrinkles on many of its bones.—Preparation of alcohol by means of sugar contained in the leaves of beets, by M. Pierre. He calculates that 34 kilogrammes of [illegible] of the leaves may yield 0·198 litre of absolute alcohol; the leaves of 1 hectare about 173 litres. At the moment of removal the leaves contained nearly 350 kilogrammes of sugar per hectare.—M. de Lesseps, presenting a *brochure* on Africa and the Geographical Conference at Brussels, explained the scheme of the King of Belgium of an international association for opening and civilising Central Africa.—On the employment of iodide of potassium in lead colic and paralysis, according to M. Melsens' method, by M. Jacobs. The patient takes 1 gramme a day, and increases the dose by 1 gramme up to 6, 8, 10, 12, or 15 grammes, then returning gradually to the initial dose. The more iodide he can bear the sooner is he cured.—Researches on the devitrification of vitreous rocks, by M. Meunier. M. Levy's facts do not seem to him to furnish any argument against the production of crystalline rocks at expense of vitreous rocks, by way of devitrification.—Results obtained by the decortication of vine stocks, by M. Sabaté.—Report on the experiments made by the Paris-Lyons-Mediterranean Company for combating phylloxera, by M. Marion. They commend sulphide of carbon and sulpho-carbonates, which should be applied when the products of the winter eggs have descended to the roots, *i.e.*, about July. The old phylloxera of the roots is thus treated as well.—Scale of platinised iridium (4 m.) of the International Geodesic Association, by M. Matthey. Observations on this communication, by M. H. Sainte-Claire Deville, also by MM. Tresca and Dumas. M. Tresca remarked on the high density, about 21·50. If it contained only 10 per cent. of iridium, $\frac{1}{1000}$ of rhodium, and $\frac{1}{1000}$ of ruthenium, the manufacture of metals of platinum must have been greatly improved since 1872.—Observation of a new star in the constellation of Cygnus, by M. Schmidt, director of the Athens Observatory.—Observations of the planet (169) Zelia, discovered at the Observatory of Paris, Sept. 28, 1876, by MM. Henry.—On the application of the methods of mathematical physics to the study of bodies terminated by cyclides, by M. Darboux.—New method for studying calorific spectra, by M. Aymonnet. With a constant heat-source, one may, even with a pretty large aperture of thermopile, find approximately the quantities of heat in spectral parts smaller than the aperture. Thus, suppose the pile is 1 mm. in aperture, you advance it (say) two-tenths of a millimetre at a time, noting each time the portion of spectrum "passed from" and the "new part" embraced. This is the principle of the method; by which M. Aymonnet gets some interesting results. The minima present a remarkable periodicity, and are displaced when the temperature of the source varies or a liquid screen is interposed.—Productions of carbonate of soda by the action of chloride of sodium in solution on carbonates of lime and magnesia, in presence of vegetable matters, by M. Pichard.—Researches on sensation compared with motion, by M. Richet. He formulates this general law as applicable both to muscles and to sensitive nerve centres: the number of excitations necessary to produce a perception or a motion is inversely proportional to the intensity and frequency of these excitations.—Experimental researches on the cardiac, vascular and respiratory effects of painful affections, by M. Franck. The immediate effect on the heat is always a stoppage or retardation of the beats.—On the form and reciprocal relations of the cellular elements of loose connective tissue, by M. Renaut.—Habits of fishes; the gourami and its nest, by M. Carbonnier.

GRAHAM'S RESEARCHES

Chemical and Physical Researches. By Thomas Graham, D.C.L., F.R.S. Collected and printed for presentation only. (Edinburgh, 1876.)

IT is but seldom that science owes a work like this to private munificence. All, therefore, to whom Mr. Graham's memory is dear will be specially grateful to Mr. James Young for choosing, as the second monument he has raised to his friend, the publication of this splendid volume.

It is fortunate also that its compilation has been undertaken by Dr. Angus Smith, who has done more than collect the scattered writings, for he has added an analysis of the contents of the volume which cannot fail to be of use, and reminds us, in a careful preface, of Graham's claim to a place in "that chain of eminent thinkers which has been represented by such as Leucippus, Lucretius, Newton, Higgins, and Dalton." As the work is printed for private circulation only, it may be well to give a brief summary of this preface which is headed "Graham and other Atomists."

A sketch is first given of the nature of Indian and Greek thought as regards atoms, and, passing to Leucippus, Dr. Smith points out that "in the mind of this early Greek, the action of the atom as one substance taking various forms by combinations unlimited, was enough to account for all the phenomena of the world." Leucippus told us that all was motion. "Graham conceived the idea that the diversity in the motion was the only basis of the diversity of the material, or that an atom constituted an element of a special kind," according to the velocity or nature of its movements. After Leucippus few men seem to have devoted much attention to the subject until modern times. A quotation from Lange gives the position assumed by Democritus, "The difference of substances arises from the difference in the number, size, shape, and arrangement of the atoms. The atoms have no internal conditions; they act by pressure and percussion only."

Dr. Smith considers that the views of Lucretius deserve attention, as he was the only full expositor of the theory of atoms to the ancients. To Lucretius atoms are "solid and eternal, with some unalterable motion." "They are made of parts, which parts cannot exist by themselves." "Motion is to him everything that can be found in life and thought, which are only the clashing of atoms." This theory allows of any shape of molecules, even hooked ones, which, as Dr. Smith somewhat dryly adds, "are spoken of as explaining combination both in Lucretius and more modern writers." Space will not permit Newton's words to be given at length, but he held that the primitive particles of which matter is composed are incomparably hard and incapable of wear, for otherwise "water and earth composed of old worn particles, would not be of the same nature and texture now with water and earth composed of entire particles in the beginning." He is thus forced to the conclusion that "the changes of corporeal things are to be placed only in the various separations and new associations and motions of these permanent particles."

A sketch is then given of the next important stage, namely, the motion of gaseous molecules, beginning with Daniel Bernoulli, and passing to Davy, Rumford, and Herapath—to whom, by the by, Graham asserted in 1863 the merit of reviving Bernoulli's hypothesis in modern times is fairly due. As is well known, the theory of gases now generally received makes them consist of small bodies continually impinging on one another, and on the walls of the inclosing vessel, their elasticity increasing with the temperature, and the pressure of the gas being due to the impact of the particles against any surface presented to them, an hypothesis which Joule investigated experimentally.

Now, as Dr. Smith shows, "it was the object of Graham's life to find out what the movement of an atom was. . . . He avoided picturing the most primitive motion in all its character, but he seems to indicate one of revolution, as he brings in the similarity to the orbit of a planet," and he advances still further, "when he adopts the theory of one kind of matter, each atom being distinguished by the extent of its motion," there being an initial impulse for each kind. "These atoms are believed to be congregate . . . and equal volumes can coalesce and form a new atomic group." Indeed the whole force of Graham's intellect was patiently and persistently devoted to this study of molecular movement, and as Dr. Smith claims him to be as "strict an anatomist as perhaps can be found," it may be interesting to gather from his writings some of the passages in which his views are expressed.

His earliest paper, on the Absorption of Gases by Liquids, was published in Thomson's "Annals of Philosophy," in 1826. In it he considers that "gases may owe their absorption in liquids to their capability of being liquefied," and that when gases appear to be absorbed by liquids, they are simply reduced to that liquid inelastic form, which otherwise (by cold or pressure) they might be made to assume; their detention in the absorbing liquid is owing to that mutual affinity between liquids which is so common. In his last paper in the *Phil. Trans.*, published forty years afterwards, he refers to the liquefaction of gas in colloids in much the same terms, for he alludes to the "general assumption of liquidity by gases when absorbed by actual liquids or by soft colloids," and he states that those gases penetrate (india-rubber) most readily which are easily liquefied by pressure, that gases undergo liquefaction when absorbed by liquids and such colloid substances as india-rubber, and finally, that the complete suspension of the gaseous function during the transit through india-rubber cannot be kept too much in view.

The *Quarterly Journal of Science*, 1829, pp. 74-83, contains his first paper on the diffusion of gases. In it he states that the diffusiveness of gases is inversely as some function of their density, apparently the square-root of the density; he also considers it conceivable that orifices of excessive minuteness may be altogether impassable by gases of low diffusive power, but defers these theoretical considerations to a future paper. This promise was fulfilled by a paper in 1831, the object of which was to establish the following law of the diffusion of gases. "The diffusion or spontaneous intermixture of two gases in contact is effected by an interchange in position of indefinitely minute volumes of the gases, which volumes are not necessarily of equal magnitude, being in the case of each gas inversely proportional to the square root of the density of that gas." He speaks of diffusion "being effected by a force of the highest intensity," and insists that diffusion takes place between the *ultimate particles of gases*, and not between sensible masses. In a later paper, *Phil. Trans.*, 1863, he states that molecules only of gas can pass the pores of graphite, "and they may be supposed to pass wholly unimpeded by friction." He showed that a gas may pass into a vacuum in four ways, first by effusion, a movement which affects *masses* of gas only, second, by diffusion which affects *molecules*, third, by transpiration through capillary tubes, "the transpiration ratios forming a class of phenomena remarkably isolated from all else at present known of gases," and lastly by a previous absorption in the walls of the septum which divides the gas from the vacuous space, as was so beautifully shown in the papers published in the years 1866-69. In one of these, in considering the passage of gas through metallic septa, he recognises "an inter-molecular porosity due entirely to dilatation at a high temperature," and thus apparently hoped to ascertain the ultimate size of molecules, for he says that this "species of porosity, if it exists, might well be expected to throw light on the distances of solid molecules at elevated temperatures."

His views are very clearly defined in a paper published in 1863 entitled "Speculative Ideas respecting the Constitution of Matter." He is of opinion that the various kinds of matter now recognised as different elementary substances may possess one and the same ultimate or atomic molecule existing in different conditions of movement. Were this ultimate atom at rest, the uniformity of matter would be perfect; but it always possesses motion, due to a primordial impulse, and, as differences in the amount of this motion occasion differences of volume, matter only differs in being lighter or denser matter. The gaseous molecule is composed of a group of the preceding inferior atoms following similar laws and is thus a reproduction of the inferior atom on a higher scale. Chemical combination consists in equal volumes of the different forms of matter coalescing and forming a new atomic molecule, and is therefore directly an affair of weight; and the combining weights differ because the densities, atomic and molecular, differ. Graham is further careful to point out that liquefaction and solidification probably only involve a restriction of the range of the atomic movement.

In this brief sketch it has not been possible to touch on his views as to states of matter, such, for instance, as the "colloidal condition which intervenes between the liquid and crystalline states," or to the more purely chemical portion of his work, of which his theory of polybasic acids is probably the most remarkable.

Widely as the value of Graham's work was recognised during his lifetime, there is no doubt that the appreciation of it is increasing, and cannot fail to be stimulated by Mr. Young's liberality, which has set forth the researches in such a manner as to impress us with their coherence and strength.

W. CHANDLER ROBERTS

THE ANDES AND THE AMAZON

The Andes and the Amazon; or, Across the Continent of South America. By James Orton, A.M., Professor of Natural History in Vassar College, U.S., &c. Third Edition, Revised and Enlarged, containing Notes of a Second Journey. Maps and Illustrations. (New York: Harper Brothers, 1876.)

AS is indicated in the title this work contains accounts of two separate journeys, to a considerable extent over the same ground, the first undertaken in 1867, the second in 1873. A narrative of the former was published several years ago both in America and in England, we believe; the second half of the volume is quite new and is essentially supplementary to the former. The results of the journey of 1867 are given in the form of a personal narrative, those of 1873 are arranged systematically in a number of chapters on the various features of the Amazon and its surroundings. The main scientific results of both expeditions have been described in the *Proceedings* of various scientific societies and in scientific journals in America and in England, and the present volume is therefore perfectly free from any details that would prove unattractive to the general reader.

In the journey of 1867 Prof. Orton and party landed at Guayaquil in Ecuador, mounted the Andes to Quito, proceeded by Papallacta, Baeza, and Archidona, still among the Andes, to the Napo river. Floating down this river they reached the Amazon, took steamer at Pebas, and enjoyed a splendid sail to the mouth of the river at Pará. In the second journey, that of 1873, Prof. Orton landed at Pará and sailed up the great river to Yurimaguas, thence over the Andes to the Pacific Coast and down to Lima, with a side-excursion to Lake Titicaca by way of Arequipa.

Prof. Orton tells his story in most attractive style. He is in danger sometimes, no doubt, of degenerating into the florid, but from beginning to end of his large volume he never ceases to be attractive, amusing, and instructive. He writes on people and things in the wonderful region of the Amazon with great piquancy, genuine humour, and full knowledge; he frequently becomes absolutely eloquent, if not poetic. Few features of the towns and the country through which he passed have escaped his attention. In describing his first journey, he lingers at Quito for several chapters, describing the city, giving hints and comments on its history, touching off the appearance and character of its easy-going people, giving an account of the country of which it is the capital, Ecuador, the flora and fauna and primeval inhabitants of the Valley of Quito, rising thence to an eloquent dramatic sketch, *à la* Hugh Miller, of the geological history of South America, the rise of the Andes, and the creation of the Amazon, devotes two interesting chapters to the volcanoes of Ecuador and its earthquakes, and before leaving, gives several details about a few of the Indian tribes in "the Province of the Orient." So on his way down the Napo and the Amazon, he paints vividly and picturesquely the scenery, the people, the animals, the plants, and the geology of one of the most interesting regions in the world. He chats pleasantly and piquantly of all he comes across, never gives the reader a chance of feeling wearied, and leaves him, if he has been a faithful listener, with a fuller and clearer knowledge of the Amazon and its tributaries, its basin, its products, its people, its cities, and fragments of towns, its industries, and its probable future, than he could get from reading many other books. The second part especially, containing the results of the journey of 1873 systematically arranged, will be found extremely handy and valuable by anyone who desires in brief space a general view of the physical geography, natural history, ethnology, industrial resources, commerce, prospects, and scenery of the vast Amazonian region. Prof. Orton has evidently supplemented his personal knowledge of the region by an extensive study of the contributions of others who have written on the subject, so that while the classical works of Bates and others, as well as the special papers of Prof. Orton himself, will be resorted to by those who desire to make a thorough study of the Amazonian basin, we know of no single work containing a fuller, more brilliantly written, and at the same time more trustworthy general account of the basin of the Amazon and its many wonders. The following extract on the density of population in the Amazonian valley will give our readers some idea of the style of the work :—

> "The valley of the Amazons is probably the most thinly-peopled region on the globe, save the great deserts and the polar zones. There are not 40,000 souls along the banks of the rivers in the whole province of Amazonas and the Lower Marañon. Many of the towns marked on the maps do not exist, or are represented by a solitary palm-hut. The visible population is almost confined to the circumference of the valley; as at Pará, near the mouth of the river; at Moyobamba and Tarapoto, on the oriental side of the Andes; and at Trinidad, Santa Cruz, Cochabamba, and La Paz, on the head-waters of the Madeira. The great basin is filled with a continuous, dark, primeval forest, rarely disturbed by the hand of man, and into which daylight seldom enters. Yet imagination peoples this pathless wilderness with uncounted swarms of savages. There are, it is true, numerous clans (we can hardly call them tribes) of Indians, distinct in language, and often hostile toward each other. But many of these so-called tribes, though dignified with separate names, are insignificant in numbers, barely mustering a hundred; while the Mundurucú, the largest known tribe in the valley, does not exceed 8,000—men, women, and children. Nor are there any remains of ancient walls to indicate a bygone civilisation, or even shell-heaps in memory of a more primitive race.
>
> "Until the close of the Tertiary age the waters prevailed over this heart of the continent; and since then vegetation has had the mastery, leaving little chance for animal life. And until there is a decided change in the physical geography of the valley, a large part of it must remain unfit for permanent settlement, on account of the annual floods; for a rise of 40 feet in the river drives the inhabitants from their summer resorts on the margin of the streams to the higher *terra firma* within the forest. In this way nomadic habits are engendered or perpetuated, and poverty is almost inevitable, for half the year (flood-time) it is hard work to get a living. Furthermore, this regular inundation of the country and the lack of grassy campos (except on the Lower Amazons and the Beni region) prevent the raising of domesticated animals, which, if it does not lie at the foundation of agriculture, certainly does aid in the transition from the savage to a semi-civilised state. In this respect the natives of Central Asia and Africa, as well as the maize-eating tribes of the Andes, have an advantage over the mandioca-eating Indians on the Amazons."

While minute criticism might find many statements and hypotheses in Prof. Orton's work to challenge; while some of his chapters may be considered by the lover of severity of style as intolerably florid; while in short anyone who has a mind to might find something to object to, we are sure that all into whose hands the work may fall will agree that few more attractive and at the same time more instructive works of travel have been written. Prof. Orton seems to anticipate that ere long the Amazon will become a highway for tourists, as it well might—even now it has a considerable service of steamers—and therefore gives many hints, directions, and statements of expense that render his work valuable as a guide-book. Not the least attractive feature are the many well-executed illustrations of places, people, scenery, and animal and plant life that enrich the volume. Two large maps, one of the Marañon and its tributaries and the other of Equatorial America, add to the value of the work, which will doubtless be brought within reach of the English reading public by some enterprising publisher.

OUR BOOK SHELF

The Secret of the Circle, its Area Ascertained. By Alick Carrick. Second Edition. (H. Sotheran and Co., 1876.)

The Impossible Problem. By James Alexander Smith. Printed for the Author's Use. (Shaw and Sons, 1876.)

THE only difference we have been able to detect between this edition and its predecessor are that the last lines of pp. 34 to 38 of the first edition are the first lines of pp. 35 to 39 of the second edition, with the corresponding changes of the other lines of the several pages, that a date has been omitted on p. 39, and fig. 2 on p. 41 slightly modified. With our copy we were favoured with a number of *The Welshman* (Sept. 29, 1876) containing a very long notice of it, supplied to the editor of the paper by an enthusiastic admirer of the work. An extract or two will sufficiently illustrate the article. "Don't let the reader run away with the idea that this is a prelude to any long, complicated calculations, understandable only by the initiated. As simple as truth itself, when ascertained, the solution of this problem is as easy and capable of absolute proof as any ordinary sum in addition and subtraction." "This beautiful problem and mystery that has tempted, attracted, and defeated the skill of thousands of the most subtle and far-seeing minds for thousands of years is found, when looked at in the right way, to be as easy and as simple as the alphabet." "It will not suffice for mathematicians to endeavour to show by any fallible and inadequate system of computation now in vogue that this result cannot be. The reader can judge for himself."

We in our former notice pointed out what we considered defective in Mr. Carrick's proof. The work is a posthumous one, hence it is that the second edition has experienced no revision at the author's hands.

Mr. Smith, in his pamphlet (8 pp.), arrives at the same result as Mr. Carrick, viz., that $\pi = 3\frac{1}{8}$, or the area of the circle equals $\frac{3}{4}$ of the square of the diameter $+ \frac{1}{32}$ of that square. The roads pursued are different.

Though we cannot agree with Mr. Smith, we have read his work with some interest, for there are some neat little pieces of simple construction in it. His equations on p. 5 may be put into the more general form :—

$$w = (3 + p)\,x,\ y = (\tfrac{3}{2} + p)\,x,\ z = (\tfrac{3}{2} + 2p)\,x.$$

We have not been able to see if other values would satisfy his equations besides the one he has selected, which leads him to draw the conclusion he does.

Concise Instructions in the Art of Retouching. By Burrows and Colton. (London: Marion and Co, 22 and 23, Soho Square, 1876.)

FOR some years past a conviction has been growing amongst the better class of professional photographers that their art alone, even under the most perfect conditions, is unable to produce an artistically perfect portrait, a proposition, by the way, for which the true artist has all along contended in the face of the constant assertion of the converse by fanatical advocates of "sun-painting" *pur et simple*. The victory having at last rested with the artists, a number of books on retouching have been published, each professing to give the true method of at once producing artistic pictures.

We are glad to see that in the present little work the authors disclaim any such intention, but, on the contrary, proceed solely to instruct their pupils in the work before them, which we may here inform the uninitiated is no less a one than that of restoring, so to speak, on a photographic negative those injuries to a face which may have been caused by imperfect lighting and defects, such as dust, &c., in the film; or disease or physical injury to the face itself. In fact, the art of the re-toucher is to convey to a photograph a certain amount of that idealisation always manifest in the works of the painter, the want of which is the unknown cause so often producing a feeling of dissatisfaction even with the best of photographs.

To carry out their aim, the authors give two very good lithographs of the muscles of the face and head, with two more of the same model covered with the flesh. Two negatives on a flexible film (apparently taken by Warnerke's process) are also added as examples of the work to be done. The descriptive matter is concisely put, and is clear and to the point. We have little doubt that the book will be of service to many amateur and professional portrait photographers.

Sea Fisheries

I HAD hoped that Mr. Holdsworth, in the rejoinder which he told me he was preparing to my former letter (NATURE, vol. xv. p. 55) would have confined himself to defending the assertions he had before made, or at most to rebutting the evidence I had adduced in reply to them. In this case I should have gladly left the matters at issue between him and me to the judgment of the public. Unfortunately he has thought it needful for the sake of the cause he adopts to introduce some new assumptions and charges, conveyed in language of a rather vigorous kind, so that out of regard to the good opinion of your readers, I am driven to trespass on their forbearance and yours. But in doing [illegible] try to be as brief as possible, and however much my friend may have exceeded the limits of a rejoinder, not to follow his example.

All will fully agree with Mr. Holdsworth that an "index is not a *précis*," but few will deny that an index is a valuable aid to mastering the contents of a book. If he says that this particular index is a bad one, I must leave him to settle with the maker of it. If it is neither bad nor good it may be misleading unless the user of it looks pretty carefully into the text. But if it is good, [illegible] it gives the reader the best of all help in acquainting [illegible] the huge volume, and by its help nobody need fear [illegible] dangerous mistakes. It does not seem to me that I [illegible] into such. The errors which my friend asserts I have made are, if errors at all, very trivial, and as one tells for, and the other against, his views, they may be safely paired off to the detriment of neither side. As to the figures set in the last column of my table, against "Cod and Ling," they ought to have been "33" instead of "38"—a mistake in copying or printing which escaped my observation till now. I freely give Mr. Holdsworth the benefit of it. The next two paragraphs of his letter have afforded me some merriment, though chastened by the thought that he must have a very low opinion of me if he seriously supposes I am ignorant of the notorious reputation of the dog-fish. Whether "predatory fishes," however, are necessarily "mischievous," so that the two epithets should be closely linked together, as though one was the consequence of the other, [illegible], upon which I shall not enter. But surely it is obvious that the prevalence of predatory fishes is more or less a measure of the prevalence of their prey, and as the blind man judged of the value of the field by asking how many thistles grew on it, so may we judge of the abundance or scarcity of other fishes by the abundance or scarcity of the dog-fish. Might I here apply to Mr. Holdsworth an expression of his own to myself, and say that, from these paragraphs, I am justified in believing him unable to comprehend one of the simplest relations of animal life?

As to herrings, I pretend to no greater knowledge of their natural history than other people do. I do not see why I should be accounted more ignorant, or attempting to conceal that ignorance, by any mysterious evolutionary process from my inner consciousness or elsewhere. The herring is admittedly not ubiquitous in the sea, *i.e.*, it has, like other animals, its more or less definite range. It therefore has "borders," though even Mr. Holdsworth cannot lay them down exactly. My friend is pleased "to doubt very much" whether I "had given five minutes' attention to the practical study of the habits of the herring—to its life-history" before I wrote my Glasgow address. That rather depends on what may be called "practical study." Has Mr. Holdsworth ever heard of a "water-telescope"—an instrument of which I can find no mention in his book—or has he ever looked through one? If, when the days get a little longer and the steamers are running conveniently, he will cross to Norway and follow the coast to the Lofoden Islands (perhaps he need not even go so far), he will possibly appreciate the value of these remarks, and will be doing what I did more than twenty years ago.

The next five paragraphs of Mr. Holdsworth's rejoinder seem to contain very fair comments on what I had urged, and, though I do not thereby assent to them, I may say that had the rest been of apiece with them I should not now be troubling you. I must, however, express my disappointment that in what follows no definite information is given as to the sea-fishes which are so often said to be devoured by sea-birds. Here is room for almost any amount of new and interesting observations, whether those observations affect his argument or not. He, not I, introduced the topic, for reasons I suppose known to himself, but not to be guessed at by me. He now seems to consider it, as I did, irrelevant.

Then as to Prof. Baird's reports. Far be it from me to find fault with my friend for fishing out the two passages which, as he thinks, tell in his favour. But these relate to two particular kinds of fishes[1]—the alewife and the cod—the former mainly as furnishing food to the latter, and I never said that to over-fishing *only* was the diminution in every case due. The decrease of the cod is ascribed by Prof. Baird to the decrease of the alewife, and this, he says, is caused by the erection in the tidal rivers of impassable dams or of weirs by means of which every fish ascending the river to spawn was caught. Surely this was "over-fishing." In the first of his reports this question is considered far more generally and closely than in the second, from which Mr. Holdsworth's extracts are taken, yet there is nothing in the [illegible] really to contradict the conclusions arrived at in the former. Hence I infer that they are still upheld by their author, and their nature may be seen by the following citations from his "General Summary of Results" (Part I., pp. 38, 39):—

"I. The alleged decrease in the number of food-fishes in these waters within the last few years has been fully substantiated.

"II. The shore-fishes have been decreasing during the past twenty years, gradually at first, but much more abruptly from about the year 1865, the reduction by the year 1871 being so great as entirely to prevent any successful summer-fishing with the hook and line, and leaving to the traps and pounds the burden of supplying the markets. This statement applies also, but perhaps to a certain extent, to the blue-fish. The decrease in their numbers first manifested itself about ten years ago, and is going on quite rapidly u[illegible] now.

"III. This period of decrease represents the time during which the traps and pounds have been well established, their operations increasing year by year, and their catch, especially in the early spring, being always very great.

---

[1] The menhaden and the mackarel are indeed mentioned, but incidentally and with some uncertainty.

. . . .

"VI. The decrease of the fish may be considered as due to the combined action of the fish-pounds or weirs, and the blue-fish, the former destroying a very large percentage of the spawning fish before they have deposited their eggs, and the latter devouring immense numbers of young fish after they have passed the ordinary perils of immaturity."

As Prof. Baird goes on to remark that there are no measures at command for destroying the blue-fish, even if that were desirable, and as the blue-fish was once far more abundant than it is at present, while other fishes were also more numerous, I cannot see that I made any mistake in stating that "over-fishing" was unquestionably assigned as "the chief cause" of the decrease in American sea-fisheries.

Lastly, Mr. Holdsworth says that the question lies between the late Royal Commissioners and myself. It was under this belief, holding him as their secretary to be their mouthpiece, that I took some trouble to reply to his first letter. Had any one not in that position challenged my remarks I should, perhaps, have not felt myself bound to give my reasons for the faith that is in me. He asserts that I have "no practical acquaintance with the subject." Possibly he considers that qualification limited to those who have been named in a Fishery Commission. In such case I certainly have none. He further charges me with using the Index to the Evidence as my "sole guide." Here I must venture to contradict him. I have used that Index, indeed, but much as Norwegian fishermen use the "water-telescope"—to look into the teeming depths of evidence below, unobstructed by the surface ripple of a Report.

To sum up. Your readers are aware that I originally treated of the Fisheries question as part of a much wider subject on which I felt constrained to speak my mind at a fitting opportunity. I have yet to learn that the Report of a Royal Commission is beyond the reach of fair and cool criticism, or that it is obligatory on all men to accept that Report as a revelation from supreme intelligence. My criticism of this Report was, I venture to think, not unfair, and it was not made in hasty warmth. Some ten years had passed since I adopted the opinions I hold, and the time had come when, as I thought, I could not help uttering them, nor does it seem to me that an unfitting occasion was offered by a meeting of the British Association. The decision of the question whether there is and has been "over-fishing" or not is hardly helped by the reiteration of the passage with which my friend ends his rejoinder.

Magdalene College, Cambridge, ALFRED NEWTON
December 15, 1876

Ocean Currents

AGREEING in the main with Mr. Digby Murray's argument on the subject of ocean currents in NATURE (vol. xv. p. 76), I am the more disposed to criticise some of the statements with which it concludes, as put forward too strongly, to say the least.

I would ask for the "absolute proof" which Mr. Digby Murray supposes to exist, that (1) the upper current return-trades "flowing from the equator descend again to the surface of the ocean on the polar sides of the calms of Cancer and Capricorn," and (2) "that these equatorial currents, subsequent to their descent on the polar sides of the calms of Cancer and Capricorn, are known as the westerly winds of the temperate zones." That these statements represent the prevailing opinion on the subject I readily admit, but I have ever looked in vain for any convincing arguments in their favour.

As regards the hypothesis that the trades cross one another in the region of equatorial calms, I may perhaps be permitted to quote some remarks of my own, made two years ago (*Symons' Met. Mag.*, vol. x. p. 37), since subsequent study has tended to confirm the doubts which I then expressed:—

"Maury's hypothesis, that the surface trade-wind of one hemisphere becomes the upper-current return-trade of the other ('Physical Geography of the Sea,' sec. 122 to 139) was in all probability originally suggested by the well-known fact that over the southern portion of the N.E. trade a S.E. upper-current prevails, and over the northern portion of the S.E. trade a N.E. upper-current, though he lays most stress on the arguments which he draws from the greater rainfall of the northern hemisphere (sec. 169 to 186), and from Ehrenberg's examination of the African air-dust (sec. 266 to 296).

"A seaman on approaching the doldrums, commonly notices a current overhead blowing at an angle of about 90° with the surface-trade; he is aware that this upper-current coincides in direction with the trade on the other side of the doldrums, and that in the calm belt itself, there is an upward motion of the atmosphere. It is, therefore, not unnatural that he should conclude that the upper-current which he observes is a poleward extension of the opposite trade in the higher regions of the atmosphere. It may also, I think, be admitted that the rapid and suddenly shifting cloud-currents, often observed over the region of the doldrums, are somewhat in keeping with Maury's idea of 'curdles,' or alternate strips of air.

"I would suggest that this hypothesis (which many subsequent writers have been surprisingly ready to adopt) may, perhaps, be subjected to a crucial test, if an answer can be given to the following query:—When the south-east trade draws so far to the north as to be deflected into a south-west surface wind, what is the prevalent direction of the upper-current over the southern portion of the north-east trade? If it runs from south-west it will be difficult to resist the conclusion that Maury is right; if from south-east it will appear probable that the upper-current is (principally at least) the north-east trade, deflected in the first part of its return course towards the north-west, just as it is in the subsequent part towards the north-east.

"Perhaps some meteorologist can give a definite answer to this question. The published data for its solution appear rather scanty; but, so far as my own limited information goes, the observations are generally rather adverse to Maury's theory."

I would now ask what proof exists that the upper currents from the polar depressions and those from the equatorial depression cross one another in the calms of Cancer and Capricorn so as subsequently to become the trades and anti-trades respectively? Since these upper-currents are understood to meet at the belts of tropical calms and there to descend, it is surely "more reasonable to suppose that their currents intermingle and that their mixed volume is then drawn off north and south, as required to restore the equilibrium of the atmosphere." These are Mr. Digby Murray's words in reference to the equatorial calms, and I fail to see why they will not apply to the calms of Cancer and Capricorn.

The whole question of the cause of the prevailing south-west and north-west winds of the north and south temperate zones, and the relation which these bear to the polar areas of barometric depression, may be regarded as fairly solved by the researches of Mr. Ferrel, Prof. J. Thomson, and others. As regards the great intensity of the Antarctic, as compared with the Arctic depression, and the superior force of the westerlies on its border, there is surely *primâ facie* ground for believing that these are mainly due to superior evaporation in the water-hemisphere generally. (I say "mainly," because it seems probable that the comparative absence of surface-friction experienced by the atmospheric currents in that hemisphere tends to intensify the Antarctic depression.) That the evaporation from the warm surface-water of the North Atlantic is in excess of that from the relatively cold surface-water of the South Atlantic, may be readily admitted; but the Atlantic represents, after all, only a small portion of the surface of the globe. Will anyone maintain that the evaporation from the whole continent of Asia is equal to that which takes place from the corresponding area of the South Indian Ocean? W. CLEMENT LEY

Solar Physics at the Present Time

HAVING now read the *Astronomical Register's* more extended account of the November meeting of the Royal Astronomical Society, I found it very confirmatory of NATURE'S shorter, but more quickly produced, summary of November 23, especially in what was said in the discussion upon Prof. Langley's (United States) paper on Sun-spots and Terrestrial Climate. Will you kindly allow me to remark:—

1. I am extremely glad that Sir G. B. Airy is now finding from the deep-soil thermometer observations at Greenwich that, whatever may be the interior temperature of the earth, and the terrific manifestations of it in some special volcanic localities abroad, yet all the remarkable changes and occasional abnormal elevations of temperature in the Greenwich soil *come from without*; for, Sir, that is precisely one of the earliest conclusions which I deduced for the Edinburgh soil, from the longer series of similar deep-soil thermometers there, and which I had the honour

of communicating to the Royal Society of London *six* years ago.

2. I am also very glad that Prof. Langley has proved by his most refined and crucial observations on the direct radiating powers of spot, penumbra and photosphere surface, combined with the continuous register of the amount each day of the spotted portion of the sun, that sun-spots have no sensible power in themselves for producing any notable change on terrestrial climate; because, Sir, in that paper of six years ago, and still in the hands of the Royal Society, I deduced that sun-spots were consequences, rather than causes, of the great periodical waves of heat which come upon the earth from without; and I proved that conclusion three times over, or for three successive cycles of the eleven-year sun-spot period.

3. As we are now on the commencement of another of those cycles, I must regret that the chief speakers seemed to intimate that almost all their idea of further investigation into the origin of those mysterious heat-waves received by the earth from without and apparently from the sun, centred in causing to be made *more sun-spot observations*; for, Sir, not only did it sound very much like proposing to lock the stable-door as soon as it should be announced that the horse is no longer therein, but there are further features accompanying those occasional great heat-waves, showing that they must originate in something much more intense, violent, and complicated than those comparatively harmless little phenomena, the dark spots. PIAZZI SMYTH,

Edinburgh, December 5 Astronomer Royal for Scotland

Radiant Points of Shooting Stars

BETWEEN October 13 and November 28, watching for forty-nine hours, I observed 367 shooting stars, 306 of which were well seen and their paths registered. On going carefully over them some thirty-five radiant points are shown, about twenty-five of which are good positions, while the remainder are open to more or less doubt. The following are the twelve principal ones:—

Dates.	Position of Radiant Point.		No. of Meteors.	Notes.
	in	at		
		R.A. Decl.		
1. Oct. 21–Nov. 20 ...	Taurus	60° + 19°	25	Many fine meteors, mean of three showers.
2. Sept. 17–Nov. 8 ...	Pisces	15 + 11	17	Mean of two showers, very slow meteors.
3. Sept. 20–Oct. 25 ...	Musca	46 + 26	19	Small rapid meteors.
4. Oct. 13–Nov. 28 ...	Lynx	125 + 47	17	White rapid meteors, mean of two showers.
5. Sept. 18–Nov. 8 ...	Cassiopeia ...	15 + 52	20	Small meteors, mean of two showers.
6. Oct. 25–Nov. 8 ...	Gemini	110 + [illegible]	11	Mean of two showers, very swift meteors.
7. Nov. 20–28	Leo Minor ...	155 + 36	21	A fine A.M. shower.
8. Nov. 20–28	Ursa Major ...	208 + 43	12	Just before sunrise, small, short meteors
9. Nov. 7–8	Camelopardus...	69 + 66	10	An evening shower.
10. Sept. 17–Nov. 20...	Lacerta	345 + 43	10	White rapid meteors, mean of two showers.
11. Nov. 22–28	Auriga	78 + 43	9	White rapid meteors.
12. Oct. 17–25	Orion...	88 + 17	8	A well-known Oct. shower.

Several of these positions are the mean of two showers, one seen in October the other in November, and evidently identical. No. 7 in the list is possibly new, and was a very active shower from near Leo; the meteors were rapid and white, leaving phosphorescent streaks. No. 8 is quite new, and three other radiants found on the mornings between November 19 and 28 are new. They are:—

Position.	R.A.	Decl.	
1. Near τ Leonis ...	170 +	4	... 6 meteors, very swift.
2. In Sextans	153 S	1	... 6 meteors.
3. α Boötis	212 +	18	... 7 meteors.

The positions given are in most cases very accurate, and each of them represents a well-marked shower. The new radiants are visible preceding sunrise, and this may account for their having previously escaped detection.

Generally the meteors of October–November were very small. The magnitudes of the 306 registered were:—

X or = 1st mag.	2nd mag.	3rd mag.	4th mag.	5th mag.	6th mag.	Total.
19 ...	49 ...	61 ...	107 ...	65 ...	5	= 306.

I have lately found meteors very much more frequent after midnight than before it. In November, 13⅜ hours watching, P.M., gave 79, while 12 hours watching, A.M., gave 133. Thus I have noted about double the number in the mornings than in the evenings. I found a similar difference in October, though have made no special comparisons to find if it has also been shown in the other months of the year. I usually find meteors show a progressive increase in numbers as the night advances, being at a minimum early in the evening hours and at a maximum just before the morning twilight.

Ashleydown, Bristol WILLIAM F. DENNING

The Atlantic Ridge and Distribution of Fossil Plants

IT has occurred to me that the discovery of the narrow belt of suboceanic highlands extending in a sinuous course down the length of the Atlantic, as shown in the *Challenger* chart, removes a difficulty that has been present to students of fossil botany. When the area was land these hills would probably form a ridge sufficiently high to have a temperature cool enough to explain the migration across the tropics of plants living in a temperate or even cooler climate. M.

Antedon Rosaceus (Comatula Rosacea)

THE letters of your correspondents with reference to the above, seem to me to fail to prove that there is any public recorded instance of its capture in the stalked (brachial) form at Torquay before the instance noted by the Birmingham Natural History and Microscopical Society in 1873. Of course if Prof. Allman took a specimen in the pre-brachial stage there in 1863, and Mr. Gosse the adult animal in 1864, the stalked form (brachial) must have been there as well, but was probably overlooked.

As to the change of name to which Mr. Thomas R. R. Stebbing objects, I certainly think that Dr. Carpenter, in his monograph before referred to, has deduced ample reasons for the substitution of *Antedon* for *Comatula*, "on the grounds of priority, in accordance with the rules of zoological nomenclature, and in concurrence with the views of Dr. J. E. Gray, Sir Wyville Thomson, and the Rev. A. Merle Norman."

Birmingham, December 10 W. R. HUGHES

"Towering" of Birds

MY experience goes to show that the towering action, although most frequent in the gallinaceous birds, is by no means confined to them. In the first case which came under my notice the bird was the common godwit. It was feeding on the border of a marsh, and I being very young at the time, committed the unsportsmanlike act of firing at it on the ground. Immediately on being hit the bird rose perpendicularly to a height of about 30 feet, then turned over on its back and fell dead almost on the spot from which it started.

Since then I have seen the same movement in the dunlin and some other species of *Tringa*, in the sanderling, the whimbrel, and, if I recollect rightly, in the lapwing plover, but in no other birds, excepting of course those mentioned by Mr. Romanes.

I have never seen a towering shore bird, after being struck, fly any considerable distance before towering, and those which have towered directly on being hit have always received a slight wound at the base of the brain, but there is little doubt that pulmonary hæmorrhage is the principal cause of this curious action.

December 12 F. W. MILLETT

THE SPECTRUM OF THE NEW STAR[1]

NOTWITHSTANDING the bad weather and the feeble light (4th to 5th mag.), I have been able to investigate pretty completely the spectrum of the light of this new star with the Eastern Equatorial of the Paris Observatory. On the first evening of observation I was only able to establish the presence of bright lines in the spectrum, two days after the atmospheric conditions enabled me to make a more thorough examination, and to take measurements as exact as the feeble light of the star permits. The following is the result of the spectroscopic investigations:—

---

[1] Sur le spectre de l'étoile nouvelle de la constellation du Cygne. Note by M. A. Cornu, read at the Paris Academy of Sciences, December 11.

The spectrum of the star is composed of a certain number of bright lines standing detached on a sort of luminous background, almost completely interrupted between the green and the blue, so that at first sight the spectrum appears to consist of two separate parts. In order to study it qualitatively, I made use of a spectroscopic eye-piece, specially constructed, which utilises the greatest portion of the light, and allows us to vary its concentration. For the measurements I employed a Duboscq direct-vision spectroscope, fitted with a scale visible by means of lateral reflection. The accompanying sketch gives an idea of the appearance of the spectrum, and represents the position of lines measured according to the readings of the auxiliary scale, in the most complete series of measurements.

I have only noticed bright lines; the dark lines, if they exist, must be very fine and must have escaped me on account of the very feeble light of the star. The order $\alpha \beta \gamma \ldots \theta$ is that of their intensity, taking into account the visibility of the colour. The following figures are the divisions of the scale which define their position:—

α	δ	γ	β	ζ	η	θ	ε
30	44	60	66	73	81	100	113

The flame of a spirit lamp, observed immediately after, gave the line D at the division 42; but a slight obliquity of the slit relatively to the lines of the scale, introduces a constant difference of one to two divisions in the direction of the re-establishment of the coincidence with the line δ.

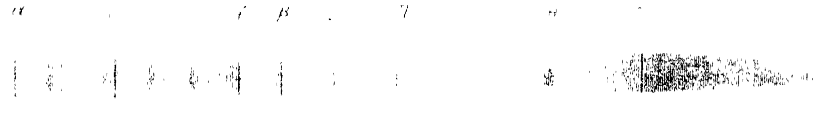
The sky being covered soon after that measurement, I left the spectroscope in position without touching it, and next morning I compared the position of the Fraunhofer lines visible with the light of the clouds:—

C	D	b (mean)	F	G
31	43·5	65·3	79·5	116

This is the spectroscope which I employed to observe the spectrum of the Aurora Borealis of February 4, 1872. The relative distance of the lines C, D, F, was the same, 21, 33, 69. There may easily be deduced from these data the correspondence of the divisions of the auxiliary scale with the scale of wave-lengths. The following are the results calculated for the bright lines observed, as also a table of bright lines of various elements expressed in millionths of a millimetre:—

	α	δ	γ	β	ζ	η	θ	ε
Observ. ...	661	588	531	517	500	483	451	435
Hydrogen ...	656(C)	—	—	—	—	486(F)	—	434
Sodium ...	—	589(D)	—	—	—	—	—	—
Magnesium...	—	—	—	517(b mean)	—	—	—	—
Line in Solar Corona ...	—	—	532	—	—	—	—	—
Line in Chromosphere..	—	587	—	—	—	—	447	—

This comparison shows that if we take into account the small apparent displacement caused by the obliquity of the slit (which makes all the numbers a little too large), and the inevitable uncertainty presented by measurements of such feeble lights, it may be admitted that the lines α, η, ε, coincide with that of hydrogen, δ with that of sodium, and β with the triple line b of magnesium. The feeble dispersing power of the spectroscope used did not enable me to distinguish whether the bright line was single, double, or triple, for any of the three cases may occur (*Comptes Rendus*, t. lxxiii., p. 332).



But the most curious coincidence, which I give here with much reserve, but which it will be interesting ultimately to verify, is the coincidence of the line γ, very bright in the spectrum of the star, with the green line λ = 532 (1474 of Kirchhoff's scale), observed in the spectrum of the solar corona and in the chromosphere; the feeble band θ corresponds also to a band λ = 447 of the chromosphere; one is thus led to think that the line δ corresponds rather to the bright line of the chromosphere λ = 587 (helium), than to that of sodium, 589. If this interpretation be accurate, the bright lines of the spectrum of the star comprehend exclusively the brightest and most frequent lines of the chromosphere. The following, in fact, according to Young's Catalogue of the Chromospheric Lines (*Phil. Mag.*, November, 1871), is [illegible]n of the brightest lines and their relative

[illegible]		587	532	517(b)	486(F)	447	434
frequence ...	100	100	75	15	100	75	100

All the other bright lines have a relative frequency lower than 10, with the exception of the fourth bright line of hydrogen λ = 410 (h), to the extreme violet, whose fre[illegible] is represented by 100. I believe, moreover, that [illegible] this line without always being able to measure it.

To sum up, the light of the star appears to possess exactly the same composition as that of the solar envelope known as the chromosphere. Notwithstanding the great temptation there exists to draw from this fact inductions relative to the physical condition of this new star, its temperature, the chemical reactions of which it may be the seat, I shall abstain from all comment and all hypothesis on this subject; I believe the facts necessary to arrive at a useful conclusion are wanting, or at least at a conclusion capable of verification. Whatever attractions these hypotheses may have, it is necessary not to forget that they are unscientific, and that, far from serving science, they greatly tend to trammel her.

JUST INTONATION

DR. STONE'S lectures on "Sound and Music," just published, lead one to expect that notwithstanding the formidable appearance of some of the key-boards exhibited at South Kensington, the cause of scientific music and of just intonation in particular will be materially advanced by the Loan Exhibition.

Certainly we may look for something practicable and little short of perfect in the "Natural Finger-board" of Mr. Colin Brown, the Euing Lecturer on Music in the Andersonian University, Glasgow. As supplementary to the descriptions given by Dr. Stone and by Mr. Brown himself, I trust the following remarks will help to elucidate the construction of the instrument, and to make still more obvious its simplicity and "naturalness."

The vibration numbers of the diatonic scale being represented by—

$$1, \frac{9}{8}, \frac{5}{4}, \frac{4}{3}, \frac{3}{2}, \frac{5}{3}, \frac{15}{8}, 2,$$

if we build the scale upon the *dominant* $\frac{3}{2}$ the vibration numbers will be—

$$1, \frac{9}{8}, \frac{5}{4}, \frac{45}{32}, \frac{3}{2}, \frac{27}{16}, \frac{15}{8}, 2,$$

and if we built it upon the subdominant $\frac{4}{3}$ the vibration numbers will be—

$$1, \frac{10}{9}, \frac{5}{4}, \frac{4}{3}, \frac{3}{2}, \frac{5}{3}, \frac{16}{9}, 2.$$

Or, more generally, if C, D, E, F, G, A, B, 2C, be taken to represent the vibration numbers of the so-named notes in the scale of C, then the vibration numbers of the scales on G and F will be—

$$C,\ D,\ E,\ \alpha F,\ G,\ \beta A,\ B,\ 2C,$$
$$C,\ \frac{1}{\beta}D,\ E, \{F,\ G,\ A,\ \frac{1}{\alpha}B,\ 2C,$$

where

$$\alpha = \frac{135}{128},\ \beta = \frac{81}{80},$$

α and β being respectively the chromatic semitone and the comma. Here the law of the formation of the relative scales is so obvious that they can be written down successively at sight.

Now let the fifteen scales be written down from C to C♯ in the one direction, and to C♭ in the other, when it will be immediately apparent that the symbols are arranged in groups of threes and fours, and if we draw straight lines horizontal and vertical so as to enclose these groups each in a rectangle, we have at once the properly so-called "Natural Fingerboard," the rectangles being the digitals, of which the larger are white and the smaller coloured

Major Keys.								
C♯	$\alpha\beta C$	$\alpha\beta D$	$\alpha\beta E$	$\alpha\beta F$	$\alpha\beta G$	○ $\alpha\beta A$	$\alpha\beta B$	$2\alpha\beta C$
F♯	$\alpha\beta C$	○ αD	$\alpha\beta E$	$\alpha\beta F$	$\alpha\beta G$	$\alpha\beta A$	βB	$2\alpha\beta C$
B	$\alpha\beta C$	αD	βE	$\alpha\beta F$	○ αG	$\alpha\beta A$	βB	$2\alpha\beta C$
E	○ αC	αD	βE	$\alpha\beta F$	αG	βA	βB	○ $2\alpha C$
A	αC	D	βE	○ αF	αG	βA	βB	$2\alpha C$
D	αC	D	βE	αF	G	βA	○ B	$2\alpha C$
G	C	D	○ E	αF	G	βA	B	2C
C	C	D	E	F	G	○ A	B	2C
F	C	○ $\frac{1}{\beta}D$	E	F	G	A	$\frac{1}{\alpha}B$	2C
B♭	C	$\frac{1}{\beta}D$	$\frac{1}{\alpha}E$	F	○ $\frac{1}{\beta}G$	A	$\frac{1}{\alpha}B$	2C
E♭	○ $\frac{1}{\beta}C$	$\frac{1}{\beta}D$	$\frac{1}{\alpha}E$	F	$\frac{1}{\beta}G$	$\frac{1}{\alpha}A$	$\frac{1}{\alpha}B$	○ $\frac{2}{\beta}C$
A♭	$\frac{1}{\beta}C$	$\frac{1}{\alpha\beta}D$	$\frac{1}{\alpha}E$	○ $\frac{1}{\beta}F$	$\frac{1}{\beta}G$	$\frac{1}{\alpha}A$	$\frac{1}{\alpha}B$	$\frac{2}{\beta}C$
D♭	$\frac{1}{\beta}C$	$\frac{1}{\alpha\beta}D$	$\frac{1}{\alpha}E$	$\frac{1}{\beta}F$	$\frac{1}{\alpha\beta}G$	$\frac{1}{\alpha}A$	○ $\frac{1}{\alpha\beta}B$	$\frac{2}{\beta}C$
G♭	$\frac{1}{\alpha\beta}C$	$\frac{1}{\alpha\beta}D$	○ $\frac{1}{\alpha\beta}E$	$\frac{1}{\beta}F$	$\frac{1}{\alpha\beta}G$	$\frac{1}{\alpha}A$	$\frac{1}{\alpha\beta}B$	$\frac{2}{\alpha\beta}C$
C♭	$\frac{1}{\alpha\beta}C$	$\frac{1}{\alpha\beta}D$	$\frac{1}{\alpha\beta}E$	$\frac{1}{\alpha\beta}F$	$\frac{1}{\alpha\beta}G$	○ $\frac{1}{\alpha\beta}A$	$\frac{1}{\alpha\beta}B$	$\frac{2}{\alpha\beta}C$

Here all the scales are true and adjacent according to their relationship, the fingering obviously the same for all. The relative minors are provided for by a round digital in the corner of each coloured digital, bearing to it the vibration ratio of 15 : 16.

The intervals on the board as seen above express themselves; moving from flat towards sharp keys the interval from a white to a coloured digital is α, and from coloured to white β.

Between digitals related as αG (G♯) and $\frac{1}{\alpha}A$ (A♭), that is, between every pair similarly related in mutual azimuth (to borrow a term) and distance, the schisma occurs. The keyboard gives us the value of the schisma by inspection; we may either take the route—

$$\frac{1}{\alpha}A \text{ to } A = \alpha : A \text{ to } G = \frac{9}{10} : G \text{ to } \alpha G = \alpha,$$

giving schisma $= \frac{9}{10}\alpha^2$. Or thus—

$$\frac{1}{\alpha}A \text{ to } A = \alpha : A \text{ to } \beta A = \beta : \beta A \text{ to } \alpha G = \frac{15}{16},$$

giving schisma $= \frac{15}{16}\alpha\beta$. This expression shows that the schisma also exists between any round digital, and the coloured digital next below. Or we may get an entirely numerical value thus:—Since from white to white is 8 : 9, then from $\frac{1}{\alpha\beta}D$ diagonally to βA is $(8 : 9)^4$ and from βA back horizontally to αC, a minor sixth, is 8 : 5, the interval of αC and $\frac{1}{\alpha\beta}D$ is

$$\text{Schisma} = \frac{5}{8}\left(\frac{9}{8}\right)^4.$$

Again, the "comma of Pythagoras" being the excess of twelve fifths over seven octaves is expressed by—

$$\left(\frac{3}{2}\right)^{12}\frac{1}{2^7} = \left(\frac{9}{8}\right)^6 \cdot \frac{1}{2},$$

that is, it is the excess of six major tones over one octave. The keyboard shows this immediately; from $\frac{1}{\alpha\beta}D$ diagonally to $2\alpha\beta C$ is six major tones, thence back horizontally to $\alpha\beta C$ is one octave, therefore $\alpha\beta C$ differs from $\frac{1}{\alpha\beta}D$ by the "comma of Pythagoras." And every pair of white digitals (or coloured, as αD and $\frac{1}{\alpha\beta}E$) similarly related in azimuth and distance have the same interval. Obviously, by mere inspection of the board, the "comma of Pythagoras" is equal to comma + schisma. In fact this keyboard will well repay a very careful study.

Turning to the practical aspect of the subject, the harmonium on this principle must be considered "un fait accompli," judging by the highly appreciative interest shown by the South Kensington audience, who remained long after the close of the lecture to listen to the instrument which was exhibited, and played on.

When we count the number of wires that would be necessary for a piano, the prospect would be somewhat alarming, did we not remember that on account of the number of harmonics and sub-harmonics, or combination tones that would be called into play, probably one wire to each digital instead of two or three would suffice.

The original account of this key-board is given in the second of two small pamphlets entitled "Music in Common Things," by Mr. Colin Brown. In these the numerical basis of the diatonic scale as derived from harmonics is laid down with remarkable perspicuity, and amongst other things the reader will see, for the first time probably, that although the fourth and sixth of the scale are wanting as harmonics to the tonic, yet they come out in the diatonic scale as harmonics to the fourth of the scale. Indeed the seven notes of the scale come out successively as harmonics to Fa in the fifth and sixth octaves.

A. R. C.

ANATOMY OF THE TEETH[1]

TO the histologist, the zoologist, and the human anatomist the teeth are organs of considerable interest, from the points of view of their minute structure, their development, together with their variations, as well as from the diseases to which they are subject; and yet our literature has been deficient in a work on "Dental Anatomy, Human and Comparative." Text-books, such as Quain and Sharpey's "Anatomy," give us full information with reference to their structure, form, and development in man, whilst in Owen's superb monograph on "Odontography," as in his "Anatomy of Vertebrated Animals," their zoological aspect is treated of in detail. Mr. Charles S. Tomes has filled the deficiency in the volume under consideration, in a manner so satisfactory that we feel assured that his work will take a high place among Messrs. Churchill's valuable "Manuals."

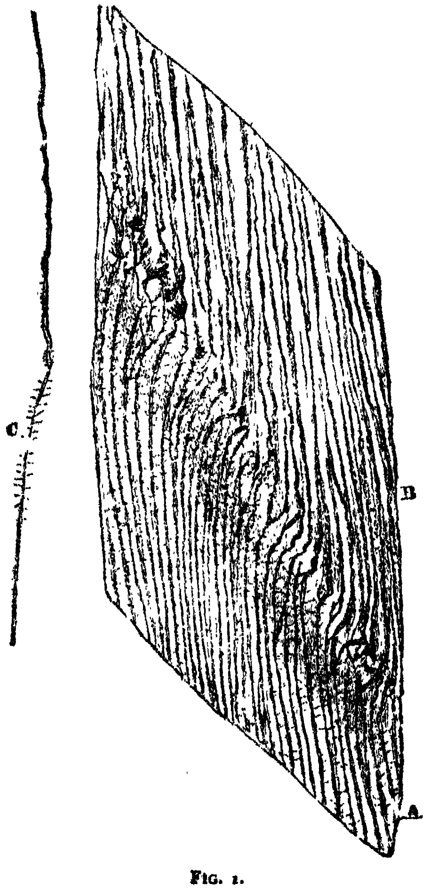


FIG. 1.

For some years past Mr. Tomes, following his father's footsteps, has been carefully investigating the structure and development of the teeth, not so much in man as in the lower vertebrata; and his results have been published in the *Proceedings* of the Odontological Society, the *Quarterly Journal of Microscopical Science*, the *Transactions* of the Royal Society, and elsewhere. In the work before us these results, many of them of considerable importance, are incorporated in the sections to which they refer, the book itself being an excellent epitome of our present knowledge of the development and structure of the teeth in man and the lower animals.

It is evident to all that a thorough acquaintance with comparative odontology cannot be obtained by anyone not familiar with the structure and development of the teeth. In the same way the facilities for investigating histological and embryological odontology are much enhanced by a knowledge of the comparative anatomy of the organs studied, as is the human dentition, although we would be among the last to make it a *sine quâ non* that our dentist should be thoroughly informed on this large view of the subject. It is, therefore, on these accounts that Mr. Tomes's Manual will appeal to more than one class of student.

The work commences with an account of the teeth of man and of the bones with which they are associated, "as being the standard with which the student is likely, consciously or unconsciously, to compare those other forms with which he afterwards becomes acquainted." The dental tissues are next described, followed by the development and eruption of the teeth, the last two hundred pages being devoted to the zoological aspect of the subject.

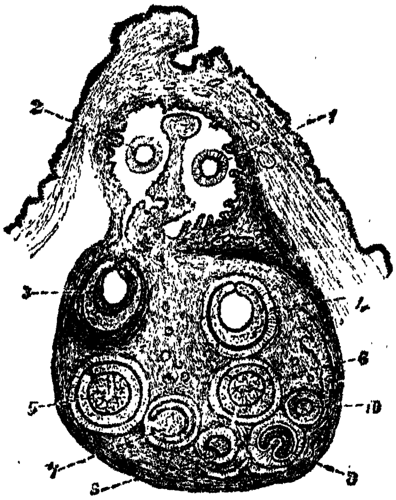

FIG. 2.

The human teeth have been studied so thoroughly that Mr. Tomes has nothing special to tell us with reference to them. As to their arrangement, his experience confirms the fact that, from the parabolic curve in which they are arranged in the typical human jaws, tending to squarish in the lowest races, "a deviation in the opposite direction is daily becoming more common in the most highly civilised races, resulting in a contour to which in extreme cases the name of V-shaped maxilla is applied."

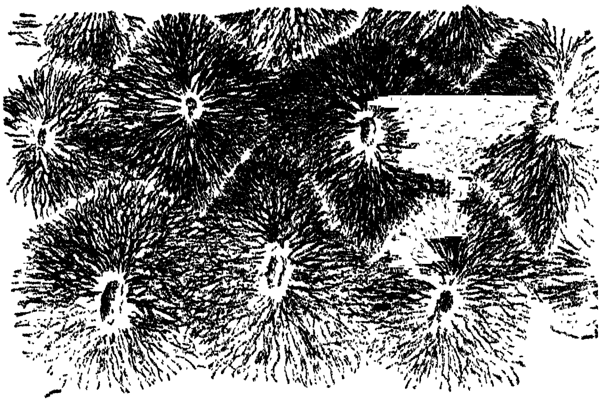

FIG. 3.

On the subject of the histology of the dental tissues we notice several interesting points. With reference to the presence of enamel in the lower vertebrata, we are told on the density and thickness of the cloud below the point from which the drops started.

---

[1] "A Manual of Dental Anatomy, Human and Comparative." By C. S. Tomes, M.A. (J. and A. Churchill, 1876.)

The author's object is to suggest that this is the actual way in which raindrops and hailstones are formed. He was first led to this conclusion from observing closely the structure of ordinary hailstones. Although to the casual observer hailstones may appear to have no particular shape except that of more or less imperfect spheres, on closer inspection they are seen all to partake more or less of a conical form with a rounded base like the sector of a sphere. In texture they have the appearance of an aggregation of minute particles of ice fitting closely together, but without any crystallisation such as that seen in the snow-flake, although the surface of the cone is striated, the striæ radiating from the vertex. Such a form and texture as this is exactly what would result if the stones were formed in the manner described above. When a particle which ultimately formed the vertex of the cone, started on its downward descent and encountered other particles on its lower face, they would adhere to it, however slightly. The mass, therefore, would grow in thickness downwards; and as some of the particles would strike the face so close to the edge that they would overhang, the lower face would continually grow broader, and a conical form be given to the mass above.

When found on the ground the hailstones are generally imperfect; and besides such bruises as may be accounted for by the fall, many of them appear to have been imperfect before reaching the ground. Such deformities, however, may be easily accounted for. The larger stones fall faster than those which are smaller, and consequently may overtake them in their descent; and then the smaller stones will stick to the larger and at once deform them. But besides the deformation caused by the presence of the smaller stone, the effect of the impact may be to impart a rotary motion to the stone, so that now it will no longer continue to grow in the same manner as before. Hence we have causes for almost any irregularities of form in the ordinary hailstone.

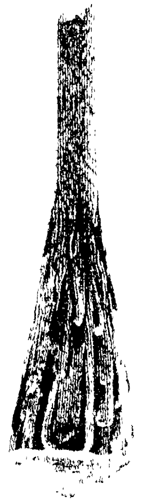

Fig. 3.—Imitation in Plaster of Paris.

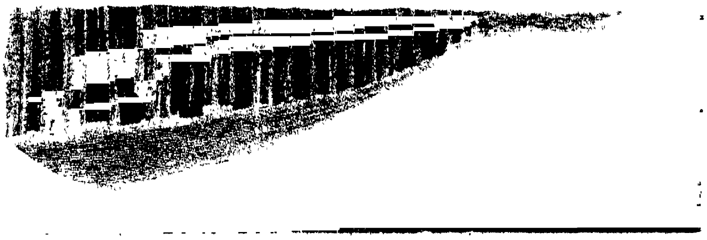

Fig. 4.—Imitation in Plaster of Paris.

It appears from the numerous accounts which have been published that occasionally hailstones are found whose form is altogether different from that described above. These, however, are exceptional, and to whatever causes they may owe their peculiarities these causes cannot affect the stones to which reference is here made.

Again, on careful examination it is seen that the ordinary hailstones are denser and firmer towards their bases or spherical sides than near the vertex of the cone, which latter often appears to have broken off in the descent. This also is exactly what would result from the manner of formation described above. When the particle first starts it will be moving slowly, and the force with which the particles impinge upon it will be slight, and, consequently, its texture loose; as, however, it grows in size and its velocity increases, it will strike the particles it overtakes with greater force, and so drive them into a more compact mass. If the velocity were sufficient, the particles would strike with sufficient force to adhere as solid ice, and this appears to be the case when the stones become large, as large as a walnut, for instance.

An idea of the effect of the suspended particles on being overtaken by the stone, may be formed from the action of the particles of sand in Mr. Tilghman's sand-blast, used for cutting glass. The two cases are essentially the same, the only difference being that the hailstone is moving through the air, whereas in the case of the sand-blast, the object which corresponds to the stone is fixed, and the sand is blown against it.

By this sand-blast the finest particles of sand are made to indent the hardest material, such as quartz or hard steel; so that the actual intensity of the pressure between the surface of the particles of sand and that of the object they strike, must be enormous. And yet the velocity of the blast is not so much greater than that at which a good-sized hailstone descends. It is easy to conceive, therefore, that the force of the impact of the suspended particles of ice if not much below the temperature of freezing on a large hailstone, would drive them together so as to form solid ice. For the effect of squeezing two particles of ice together, is to cause them to thaw at the surface of contact, and as soon as the pressure is relieved they freeze again, and hence their adhesion.

It is then shown that hailstones, such as those described, can neither be formed by the freezing of rain-drops, nor by he condensation of vapour on a nucleus of ice; and that t is impossible that the particles of ice can have been rawn together by electrical attraction—their conical hape, and the increase in their density towards their hicker sides clearly showing that the particles have aggreated from one direction, and with an increasing force as he size of the stone has increased.

The possibility of making artificial stones is thus conidered:—If a stream of frozen fog were driven against ny small object, then the frozen particles should accumulate on the object in a mass resembling a hailstone. Not eeing his way to obtain such a stream of frozen fog, the uthor thought it might be worth while to try the effect of lowing very finely powdered plaster of Paris. He thereore introduced a stream of this material into a jet of team, issuing freely into the air (which he hoped would noisten the powdered plaster sufficiently to cause it to set rmly into whatever form it collected). The jet was lirected against a splinter of wood.

In this way masses of plaster very closely resembling ailstones were obtained. They were all more or less onical, with their bases facing the jet. But as might be xpected, the angles of the cones were all smaller than hose of the hailstones. Two of these figures are shown n the sketches annexed:

The striæ were strongly marked, and exactly resembled hose of the hailstone. The bases also were rounded. They were somewhat steeper than those of the hailstone; ut this was clearly due to the want of sufficient cohesive ower on the part of the plaster. It was not sufficiently vet. Owing to this cause also it was not possible to preerve the lumps when they were formed, as the least shake aused them to tumble in pieces.

Similar masses were also obtained by blowing the 'apour of naphthaline, but these were also very fragile. Whereupon it is remarked:—At ordinary temperatures he powdered naphthaline does not adhere like ice when ressed into a lump. No doubt at very low temperatures ce would behave in the same way, that is to say, the articles would not adhere from the force of impact. Hence it would seem probable that for hailstones to be ormed, the temperature of the cloud must not be much elow freezing-point.

That the effect of the temperature of the cloud exerises great influence on the character of the hailstones annot be doubted. And if, as has been suggested by M. L. Dufour, the particles will sometimes remain fluid, even when the temperature is as low as 0° F., it is clear hat as they are swept up by a falling stone, they may reeze into homogeneous ice either in a laminated or rystalline form.

The author then proceeds to show that raindrops are robably formed in the same way as hailstones; that lthough the raindrops have no structural peculiarities ike the hailstones, the aggregation of the particles of vater by the descent of the drop through the cloud is the nly explanation which will account for them. He shows hat, as Mr. Baxendell had previously pointed out, the mount of vapour which a cold drop could condense efore it becomes as warm as the vapour would be inappreciable when compared with the size of the drop, nd since, in order that there might be condensation, the ir must be warmer than the drop, the drop could not art with its heat to the air. He also shows that during he time of descent of a large drop, the heat lost by adiation would not account for the condensation of sufcient vapour to make any appreciable difference in the ize of the drop. Whereas if we suppose all the vapour which a body of saturated air at 60° F. would contain ver and above what it would contain at 32° to be changed nto a fog or cloud; then if a particle, after commencing o descend, aggregated to itself all the water suspended in he volume of air through which it swept, the diameter of he drop after passing through 2,000 feet would be more than an eighth of an inch, and after passing through 4,000 feet a quarter of an inch, and so on. So that in passing through 8,000 feet of such cloud, it would acquire a diameter of half an inch.

The fact that raindrops never attain the size of large hailstones is explained as being due to the mobility in the case of large drops of the surface tension of the water, by which alone the drop retains its form, to withstand the disturbing force of the air rushing past; when the drop reaches a certain size, therefore, it is blown in pieces like the water from a fountain.

The origin of drops and stones is then discussed—why some of the particles in a cloud should be larger than the others, as it is necessary for them to be in order that they may commence a more rapid descent. A cloud does not always rain; and hence it would seem that in their normal condition the particles of a cloud are all of the same size and have no internal motion, and that the variation of size is due to some irregularity or disturbance in the cloud.

Such irregularity would result when a cloud is cooling by radiation from its upper surface. The particles on the top of the cloud being more exposed would radiate faster than those below them and hence they would condense more vapour and grow more rapidly in size. They would therefore descend and leave other particles to form the top of the cloud. In this way we should have in embryo a continuous succession of drops.

Eddies in the cloud also form another possible cause of the origin of drops and stones.

D'ALBERTIS'S EXPEDITION UP THE FLY RIVER, NEW GUINEA

RECENT letters from Sydney announce the successful results of Signor L. M. D'Albertis's expedition up the Fly River, and that he was shortly expected back in Sydney.

The following letter from him to Dr. George Bennett has been published in the Sydney newspapers of October 13:—

"DEAR DOCTOR,—I have written a letter to the Committee, necessarily very brief, as I have but little time and a very scanty supply of paper. I am satisfied with the collection I have made, not for the number, but for the quality. I have four species of birds of paradise (*Paradisea*), the *P. raggiana*, the *P. apoda*, the twelve-wired bird of paradise (*Seleucides alba*), the king bird of paradise (*Cincinurus regius*), and the rifle bird (*Epimachus magnificus*). I got a perfect adult specimen of a cassowary, which I think is *Casuarius bicarunculatus*; also the *Dasyptilus pecqueti*, a new genus of *Ptilotis*, and a splendid new species of *Gracula*, and several other small but very interesting birds. I have seen many birds which are not included in the avifauna of New Guinea, as the *Pelecanus conspicillatus*, the Jabiru (*Mycteria australis*) and the pygmy goose (*Nettapus pulchellus*). Among my fishes I have some fine and large species. Of reptiles I have very few except a water snake, which I hope will be something extraordinarily new. Among my insects I have some fine Coleoptera, but the season was not very favourable for them. I expect to have about five hundred species of dried plants and between twenty and thirty of living plants, collected far in the interior, many of which I did not get afterwards. I hope Mr. C. Moore will be satisfied, as I have some fine crotons and palms among them, also some ferns with variegated leaves, orchids, and several other plants with variegated or spotted foliage, &c., from the very centre of New Guinea. I hope Mr. Moore has sent to Somerset some Wardian cases, so that the plants may not be destroyed by the sea breezes during the passage to Sydney. I much regret that I cannot send you any specimens, but I have not a box to pack them in; the few boxes I have are filled with earth and living plants. My ethnological collections are very extensive indeed; I have literally cleared all the houses, and I have the best collection of the stone implements of New Guinea ever seen, of every kind and description. I have also the ornaments used when dancing and when engaged in war, paddles for their canoes, &c., &c. I procured dresses of various patterns, some petticoats made of human hair, others of grass, both of the natural colour and dyed; stone implements, finished and unfinished; painted and carved skulls, stuffed human heads, arrows pointed with bone, artistically worked, and the cement used in fixing the points. I am very anxious to show you everything, and see your surprise at the beauty of my collection, as you can so well appreciate it. I hope my plan of the Fly River will be correct. I have noted mile by mile, and every day I landed I recorded the nature of the soil, &c. I hope the Government, Committee, and subscribers to the Expedition will be satisfied with the confidence they placed in me, and, more so, when I have time to publish my notes *in extenso*. I have investigated science in all its various branches, more especially anthropology. The presence of the great bird of paradise (*Paradisea apoda*, Linn.) in the centre of New Guinea, but at the same time in almost the same latitude as Aru Island, is of the greatest importance after what Lesson has asserted, and which has been denied by Wallace. I have got specimens in every stage of plumage, and of both sexes, and I have no doubt it is the *P. apoda*, and not the *P. papuana*. It is, nevertheless, much smaller than all the specimens I have seen in the British Museum, and in the collections of Mr. Beccari and Mr. Cockerell, and if with this distinction, when compared, any other difference may be perceptible, then it will probably prove to be a new species. For the present I believe it to be the *Paradisea apoda*. I have two beautiful male birds in full plumage, and also of the *P. raggiana*. I hope the Committee will be pleased with the short report I have sent, but at the same time must ask them to suspend their judgment of all that I have done until they receive a more extended and minuter account of the expedition from me." [Mr. D'Albertis concludes his letter with a few lines addressed to Mrs. Bennett, in which he says]: "I am in good health and spirits, and remember your kindness, for I bought bananas, when I was starving, with the red worsted ribbons adorned with pearl shells you gave me to traffic with the natives. I also enjoyed the large plum cake for a month, and finished it in the true centre of New Guinea, and wished I had another. The flag was the admiration of the natives of Moatta, and I bore in remembrance the ladies who presented it to me."

P. L. S.

OUR ASTRONOMICAL COLUMN

THE NEW STAR IN CYGNUS.—It is stated by Prof. Littrow (*Bulletin International*, December 12) that this star, which on December 1 appeared of about the same brightness as at the time of discovery on November 24, was of the fourth magnitude on December 2, and two days later had descended to the fifth.

Comparisons with neighbouring stars, using the magnitudes of the "Durchmusterung" on December 13, showed that the estimate we gave last week was somewhat too low, being doubtless influenced by the unfavourable conditions on the previous night; the star was found to be 5·8—6·0, but as before, without trace of colour.

The following position for 1876·0 will be rather closer than the one given last week, R.A. 21h. 36m. 50·41s., N.P.D. 47° 43′ 21″·5, to which correspond annual precession in R.A. + 2·361s., in N.P.D. − 16″·27. We give M. Cornu's spectroscopic results in another column.

REMARKABLE STAR SPECTRUM.—D'Arrest, writing in November, 18[illegible], refers to the spectrum of the star XX. 1206. of Weisse's second catalogue from Bessel's zone observations; he says "sein Spectrum ist das *merkwürdigste unter einigen tausenden*, die ich bislang untersucht habe," and thinks the star may eventually prove to be varinble. Has this object been examined by any British spectroscopist? It was observed by Bessel as an eighth magnitude, October 26, 1823, and his position reduced to 1877·0 is in R.A. 20h. 43m. 24·2s., N.P.D. 67° 27′ 36″.

THE MINOR PLANET, NO. 169.—This last discovered member of the group of small planets which was detected at Paris on September 28, has been named "Zelia." M. Leverrier's *Bulletin* of December 12, contains ample materials for the determination of its orbit.

NEWCOMB'S CORRECTIONS TO HANSEN'S LUNAR TABLES.—Part III. of papers published by the United States Commission on the transit of Venus, just received, contains an important investigation, by Prof. Newcomb, of the corrections required by Hansen's lunar tables, for the purpose of rendering the lunar ephemeris available for accurate determination of the longitudes of stations not telegraphically connected with well-ascertained positions.

Remarking that determinations of longitudes from moon culminations have been found by experience to be subject to constant errors which there is difficulty in allowing for, Prof. Newcomb refers to its having been a part of the policy of the American Commission to depend rather upon occultations. An occultation of a star is a sudden phenomenon, and the time at which it occurs can be fixed by observation within a small fraction of a second; wherefore, if the ephemeris of the moon is exact and her figure a perfect circle, the longitude could be determined from such observations with a similar degree of precision. The inequalities of the lunar contour form a source of error that it is impossible to avoid, but may be considered to be eliminated from the mean of a large number of observations, and the star's position admitting of being fixed by the meridian instruments with any required exactness, there remain only the errors of the lunar ephemeris to be diminished as far as practicable, and it is the object of Prof. Newcomb's paper to reduce these errors to a minimum.

The material principally relied upon is the series of meridian observations of the moon at Greenwich and Washington from 1862 to 1874, but in order to verify the most striking and unexpected result of the investigation, the comparison of Hansen's tables with the Greenwich observations during the twelve years 1847-1858 has also been utilised. The result alluded to is the irregularity in the moon's longitude represented by

$$1''\cdot50 \sin (56^\circ\cdot8 + 13^\circ\cdot12413t)$$

where t is reckoned in days from Greenwich mean noon of 1850, January 0. The period of this inequality is 27·4304 days.

Prof. Newcomb remarks that "it would perhaps be premature to introduce so purely empirical a term as this into lunar tables for permanent use," but in the particular case to which his researches apply, where it is requisite to obtain the corrections of the tables with all possible accuracy for a limited period only, he considers the evidence in favour of the existence of the inequality sufficiently strong to justify its introduction. He further observes that the only apparent cause for this term is "the attraction of some one of the planets."

Prof. Newcomb finds some support to a correction of the tabular longitude of node, as already suggested by Hansen in the *Darlegung* in connection with his discussion of ancient eclipses. The entire corrections to the moon's longitude given by his investigation are given at p. 37, supplemented by auxiliary tables for facilitating the calculation of the corrections required by the tables as published, the arguments in which extend from 1850 to 1800.

It will be remembered that Prof. Newcomb communicated his principal result to the Royal Astronomical Society last summer (see "Monthly Notices," vol. xxxvi. p. 358).

Prof. Förster's Scientific Lectures.—Under the title *Sammlung wissenschaftlicher Vorträge*, there has lately appeared a series of seven lectures on astronomical subjects by the director of the Royal Observatory at Berlin. It includes an address on "The Astronomy of Antiquity and the Middle Ages in Relation to Modern Development," notices of Copernicus and Kepler and their works, &c.

CHEMICAL NOTES

Variations in the Critical Point of Carbon Dioxide in Minerals, and Deductions from these and other Facts.—Mr. W. N. Hartley has continued his experiments on this subject, and gives in a paper read lately before the Chemical Society further conclusions as to the existence of the expansible fluids in mineral cavities. He concludes it to be carbon dioxide from the spectrum produced by the electric spark in a tube containing such gas as was liberated by the decomposition of the minerals; the turbidity produced by crushing quartz under baryta water (Vogelsang and Geissler, 1869); the rate of expansion of the liquid in sapphire compared with that of carbon dioxide (Sorby and Butler, 1869) and the determinations of the critical point made by himself in 1875-76. To determine the critical point he uses small thermometers made specially for the purpose, one having a range from - 20 to 140° F., the other graduated to register tenths of a degree from 25° to 33° C. The following table shows all the variations noticed in the critical point of carbon dioxide existing in various minerals:—

	Critical point.
Topaz	28° C.
Topaz	28° C. and 26°·5
Topaz	27°·55
Tourmaline	27°·27
Tourmaline	26°·9
Sapphire	between 30°·5 and 31°
Sapphire	between 25·5° and 26°
Sapphire	29°·5
Rock crystal	30°·95
Rock crystal	30°·95
Rock crystal	32°·5
Rock crystal	33°·7
Rock crystal	39°
Rock crystal	30°·95
Beryl	30°·92

He discusses, from his conclusions, certain ideas with regard to the formation of diamonds, and believes that it is difficult to suppose that they are entirely formed by a process in which unoxidised forms of carbon are intermediate products, otherwise they would occur not unfrequently in the neighbourhood of coal formations. The theory that diamonds are produced by reducing agents on carbon dioxide very highly compressed and acted on at temperatures much above its critical point, introduces a condition of things highly suggestive of further speculation, and of experiments subject to conditions under which no chemical reactions have ever been made in the laboratory.

Thermo-Chemical Researches.—Julius Thomsen has found in some recent investigations that gold presents allotropic modifications according to the nature of the solutions from which it is obtained, and the reagent with which it is precipitated. The modifications he has examined are gold precipitated from solution of the chloride and bromide respectively by sulphurous acid, and that precipitated from the sub-chloride, sub-bromide, and sub-iodide. These modifications differ in the amount of heat evolved by each in similar reactions. As the energy shown by the gold precipitated from solution of the chloride by sulphurous acid is less than in the other cases, this amount is taken as the standard. The energy of the gold precipitated from the bromide is greater by 3·200 heat units, and that precipitated from the sub-chloride, sub-iodide, or sub-bromide by 4·700 heat units per atom.

Theine in Tea.—As the amount of theine varies in various kinds of tea (according to different analyses) from one to six per cent., the question naturally arises whether the quality of tea does not depend upon the amount of theine it contains. Some time ago M. Claus arrived at the conclusion that the inferior kinds of tea contain altogether more theine than the higher, pointing out especially that the cheapest, the so-called brick-tea used in Mongolia and Siberia, and prepared from all kinds of refuse as dead leaves, stalks, &c., contains far more theine (3·3 to 3·6 per cent.) than the higher qualities (1·0 to 1·3 per cent.). M. Markovnikoff, of Moscow, now arrives at different results. Having made a series of analyses of one kind of tea by the various analytical methods used until now, for ascertaining their comparative values, he proves the deficiency of most of these methods. Ether, for instance, extracts but one-third of the whole amount of theine, and benzole, one-fourth. Using, then, a more perfect method, and analysing six kinds of tea, selected from the highest and from the lowest qualities, he arrives at the result that the amount of theine in them varies but very little, from 2·08 to 2·44, and that it regularly increases, with one exception, with the quality of tea, whilst the amount of ash given by each kind regularly decreases from 6·1 to 5·7 per cent. The differences being, however, very small, M. Markovnikoff supposes that the quality of tea does not depend, or depends very little, upon the amount of theine, and far more upon the quantity of tannic acid and aromatic oils it contains, but that on the whole the teas made from younger leaves contain more theine than those made from older leaves.

Influence of Pressure on Combustion.—Some interesting observations have been recently made by M. Wartha, on the influence of pressure on combustion. He observed the burning of six stearine candles in free air, and in an iron case under a pressure of 1·95 atmospheres. They burned under this pressure with a flame 9 to 12 cm. long, and gave much smoke; their luminous power diminished, while the flame assumed a yellowish-red colour. The decrease of weight after one hour of burning was found to be less than in burning in free air. This last result is opposed to the observations of Frankland, who has affirmed that the consumption of the burning material of a candle, or the like, is not perceptibly dependent on the pressure of the medium in which the combustion occurs. It is supposed that the difference of pressure in Frankland's experiments (on Mont Blanc and at Chamounix) was not sufficiently great to give a distinct difference in consumption of the burning matter. M. Wartha further put a candle to burn under an air-pump receiver, with special apertures, and, with increasing rarefaction, the flame was seen to enlarge, and its luminous power to diminish. At a pressure of 90 mm., the greatest rarefaction produced, the luminous power was quite gone, and the flame, which had now assumed threefold size, appeared to consist of three parts, an inner bluish-green cone with a violet sheath, and a weakly violet mantle. The diminution of the luminous power in this case M. Wartha explains by the fact that under less pressure less of the products of combustion are separated in the form of soot.

BIOLOGICAL NOTES

The American Bisons.—An important quarto memoir on the living and extinct Bisons of America, from the pen of Mr. J. A. Allen, has just been issued from the University Press of Cambridge, Massachusetts. It is illustrated by twelve plates and a map of North America, in which the distribution of the bison at different dates is indicated by various colours. The material for the account of the fossil forms, namely, *Bison latifrons* and *B. antiquus*, was obtained by Mr. N. S. Shaler, the Director of the Kentucky Geological Survey during 1868 and 1869, at Big Bone Lick. Independent of its scientific interest the description of the chase and rapid diminution of the existing animal will be found well worthy of perusal.

Coloration of Water by Salpæ.—Coral reefs, as is well known, give a greenish appearance to the surrounding water when they do not lie far below the surface of the sea. The captains of merchant-vessels are accustomed to report the observation of such spots in the ocean when they are not marked on the charts. It has, however, frequently occurred, that subsequent navigators are entirely unable to find at such points any trace of hidden reefs. Baron von Schleinitz, commander of the German vessel *Gazelle*, in the report on his late exploring expedition, mentions that he encountered ten such places in the meridian 177° E. and 31° S. The lead was sunk to distances varying from 400 to 600 feet, at all these places, without reaching bottom. The green water presented an appearance as if an oily liquid was constantly rising to the surface, and a quantity of it was secured for examination. Investigation showed the cause of the phenomenon to be the presence of a great number of small, transparent, spherical salpæ. These were joined together in double rows of seven each, and by simultaneous expansion and contraction maintained a regular and comparatively rapid motion.

The Evolution of the Camelidæ.—Prof. Cope traces an acceleration of the process of ossification of the cannon bones in Camelidæ, by which the three constituent metapodials become united at earlier and earlier periods of life. In the oldest genus, Poëbrotherium, these bones are permanently distinct; they are long distinct in Procamelus; and in Auchenia the bones are united before birth. There has been a concurrent reduction of the incisor teeth. In the Soup Fork genus Protolabis the three superior incisors persisted throughout life. In *Procamelus occidentalis* the second of these teeth persisted without being protruded till nearly adult age; the first incisor was very small, and, with its alveolus, was early removed. In the existing Camelidæ the second incisor disappears in the same way. In ruminants other than Camelidæ the third or external incisor has undergone the same process, while in the Bovidæ the canines have also been atrophied.

Self-Fertilisation of Plants.—Mr. Thomas Meehan, continuing his observations on this subject, has found that the flower of *Campanula pulcherrima*, when confined in fine gauze bags, seeded perfectly; the method of this self-fertilisation he has not discovered. He has observed the self-fertilisation of chicory, which has rather large white pollen grains. The whole process takes about two hours. About six o'clock in the morning the pistil with closed stigmatic lobes elongates, pushing through the mass of pollen and carrying quantities with it. About an hour after the stigmatic lobes expand, and the pollen falls into the cleft and on to the stigmatic surface. The flowers close entirely by nine or ten o'clock of the same day. No doubt pollen-eating insects visited the flowers, but when these were carefully excluded, all the flowers had pollen on their stigmatic surfaces, nevertheless. (*Proc. Acad Nat. Sci., Philadelphia*, 1876, p. 142.)

An Unusual Case of Natural Selection.—The usual causes for the origin and increase of secondary sexual characters do not exist among gasteropods; there is no struggling between the males for possession of the females. Mr. E. S. Morse has described (*Proc. Boston Soc. Nat. Hist.*, 1876, p. 284) a curious case in which in a limited area the shells of the males of *Buccinum undatum* scarcely equalled half the length of the female shells, and there was no doubt about their maturity. The rocky ledge on which they lived was at all times washed by impetuous currents, and the specimens of Buccinum were always found hid in nooks and concealed in cracks and crevices. Only the smallest males could work their way into such constricted quarters to the females; thus a diminution of the normal size of the male had arisen from a singular secondary sexual cause.

Gelatine in Relation to Nutrition.—Proceeding from the supposition that the processes of digestion are merely decompositions under the influence of water, which furnishes smaller and more diffusible molecules, that are afterwards compounded into the constituents of the body, M. Hermann recently (*Naturforscher*) proposed the question whether it might not be possible to employ gelatine for synthesis of albumen in the system (its decomposition products being very similar to those of albumen), merely adding tyrosin to it, the products of albumen-decomposition which are wanting. He accordingly requested M. Escher to make certain experiments on the subject. For a number of days the same food, containing gelatine but no albumen, was given to animals, and their weight and urine were determined. Then, for a similar number of days, the same amount of food was given, with a small quantity of tyrosin added, and weight and urine again determined. If the above supposition were correct, the body-weight should diminish during the first period, and the excreted urine correspond to the gelatine taken, plus some albumen of the body; in the period in which tyrosin was given, the body-weight should decrease less quickly or not at all, or even increase, and the urine be diminished so much as would correspond to the quantity of gelatine retained in the body together with tyrosin, like albumen. The experiments (nine series of them) made on pigs and dogs gave the following results:—1. Gelatine and tyrosin are absorbed in the intestine; they do not appear again in the excrement. 2. In food containing no albumen, gelatine alone cannot sustain the animal organism; the weight diminishes. 3. The same holds for tyrosin in food that is without albumen. 4. In food without albumen, gelatine and tyrosin may together sustain the organism; the weight of this remains stationary, or even increases. 5. The addition of tyrosin to food containing gelatine, but no albumen, diminishes the excretion of urine, so that less nitrogen is excreted than taken.

NOTES

Next month a new mineralogical journal will appear in Germany to be called *Zeitschrift für Krystallographie und Mineralogie*. The editor is Dr. Groth, Professor of Mineralogy in the University of Strassburg. The most eminent German and foreign mineralogists have promised their co-operation.

The *Nation* states that the Trustees of the Johns Hopkins University are prepared, if convinced of the want of such a periodical, to assist in the publication of an American *Journal of Pure and Applied Mathematics*. A circular to elicit an expression of views on this subject has been issued under the signatures of Professors J. J. Sylvester, Simon Newcomb, Henry A. Rowland, and William E. Story.

Messrs. Macmillan and Co. are about to publish the first volume of a "Treatise on Chemistry" by Prof. Roscoe and Dr. Schorlemmer. The aim of the authors in this work has been to furnish a concise but at the same time complete treatise, which they hope will serve as a standard for the use of those who desire to obtain a more extended knowledge than can be derived from the various excellent smaller manuals that exist. The authors endeavour to give as complete and accurate an account as possible of purely chemical phenomena, and a clear description of the chief chemical processes. In the case of each element and of the chief compounds a short historical statement of the growth of our knowledge is prefixed to the description of their chemical properties, while in all cases of importance references to original memoirs are given. Special care has been bestowed upon the illustrations.

THE following are the arrangements for the Friday evening lectures at the Royal Institution:—January 19, Prof. Tyndall, LL.D., F.R.S., M.R.I.; January 26, Prof. Huxley, LL.D., F.R.S.; February 2, Prof. Osborne Reynolds, "Vortex Motion;" February 9, Francis Galton, F.R.S., M.R.I., "Typical Laws of Heredity;" February 16, Prof. F. Guthrie, F.R.S., "Solid Water;" February 23, J. F. Moulton; March 2, Sir John Lubbock, Bt., M.P., F.R.S., M.R.I., "Ants;" March 9, Frederick J. Bramwell, F.R.S., M.R.I.; March 16; March 23, Prof. Gladstone, Ph.D., F.R.S., M.R.I.

M. LEVERRIER is setting up, at the door of the Paris Observatory, a public clock for the use of clock-makers, who have been in the habit of calling at a special room to see a chronometer regulated for their use. He has also issued a circular announcing that every commune which purchases a public aneroid barometer, places it for inspection in a public building, and enters into an engagement to send regularly weather telegrams, will receive warnings, either directly from the Observatory, or through a departmental office established in each chief centre.

A LARGE aneroid barometer has been placed in the most prominent part of the Paris Halles for the use of the country people who come daily to sell their garden produce. The dial is 1 metre 50 in diameter, and is lighted at night.

AT the last meeting of the Netherlands Zoological Association (held on Saturday, November 18, in the Zoological Garden of Rotterdam) the Committee of the Transportable Zoological Station (see NATURE, vol. xv., p. 118) presented their first annual report, which was received with enthusiasm by the members of the Association, and will be printed in its *Bulletin*. Next year Flushing will see the station erected in its neighbourhood. With the addition of a fourth member, the Committee of the past year was re-elected for the year 1877, and consists now of Prof. Hoffmann (Leiden University), Dr. Hock (Assistant at the Leiden Zootomical Laboratory), Dr. Hubrecht (Conservator Leiden Natural History Museum), and Dr. Horst (Assistant at the Utrecht Zootomical Laboratory).

No less than twenty-nine medical men have been elected members of the French Chamber of Deputies, and seven members of the Senate. One of these, Dr. Henry Liouville, suggested the establishment of an extra Parliamentary Conference of all his colleagues. The idea was carried into execution, and the conference of medical legislators has produced much useful work. Various important bills have been already prepared and presented to the Chamber of Deputies by these medical members. The object of the Conference is merely to deliberate upon medical matters, all political subjects being excluded. Members of all parties are admitted if they belong to the medical profession. The meetings of the Medical Conference are held weekly at the residence of Dr. Henry Liouville.

A PARISIAN optician recently commenced to observe daily the exact times at which a radiometer in his shop began and ceased to rotate. The results are published daily in the *Temps*, and although different radiometers cannot well be compared with each other, these results are already interesting. Since December 1, when the first notice was published, the radiometer stopped twice entirely during the daytime—on the 8th, during a thunderstorm, which lasted from 1.30 to 3 P.M., and on the 13th, from 10 to 10.45 A.M., during an obscuration produced by fogs. The exact time of the first move varies from 8.15 to 10.25 A.M. according to the purity of the atmosphere. The time of stopping is far less irregular, having varied only from 3.30 to 4 P.M.

THE hall in which the Academy of Sciences meets seems to be one of the worst ventilated rooms in Paris. If the windows are closed the members are stifled with heat and foul air, and many of the members have a horror of open windows. An illustrious physiologist is specially remarkable for his aversion to a current of fresh air. At a recent sitting the following colloquy on this subject occurred:—"M. Bouley: Nous sommes plongés dans un air irrespirable; ce n'est pas tenable; et, au lieu du gaz, je désire qu'on nous rende les anciennes bougies. M. Leverrier: J'ai réclamé l'éclairage par le gaz; mais j'avais réclamé aussi un autre mode d'aération. Or, rien n'a été changé sous ce rapport. Cependant nous avons le général Morin, et en huit jours des appareils convenables de ventilation seraient installés, si l'on voulait. M. Morin: Ah! en huit jours! Il y a dix ans que leur installation est décidée en principe!!! M. Leverrier: L'état actuel est vraiment honteux! Il n'y a pas de salle aussi mal ventilée que la *salle de l'Institut!*" If M. Leverrier would enter the meeting-room in the magnificent new buildings of the Royal Society during a meeting of that learned body, perhaps he would be inclined to modify his statement. It is a curious commentary on the progress of science that in Paris and London the most unscientifically constructed buildings are those in which the leaders of science carry on their deliberations.

BARON VON HOFMANN, president of the Oriental Museum in Vienna, has received a letter from the Austro-Hungarian Consul at Khartoum giving some details of the travels of Emin Effendi (Dr. Schnitzer). He has visited Uganda, Usoga, and Unyora, and stayed for some time with King Mtesa, whom he speaks of as a most wonderful man, with a considerable proportion of Abyssinian blood in his veins. This mixture of Abyssinian and negro blood Dr. Schnitzer is inclined to think accounts for the varied traits of character which travellers tell us Mtesa exhibits. He speaks of him as a man of high intelligence, but like all negroes, a child with tiger instincts; his liking for Christianity may possibly be an outcome of his Abyssinian blood. Dr. Schnitzer states that if he gets safely to the end of his journey through Nasiudi, Magango, over the lake to Duffli and Lado, he will set about the arrangement for publication of his well-filled diaries. Dr. Noll of Frankfort will publish the zoological results of his travels.

A COMMISSION for the investigation of the possibility of making a canal across the Isthmus of Darien, left St. Nazaire last month. If their report is favourable it is stated that the work will be commenced next year.

A SPECIAL society for sending a scientific and commercial expedition to the unexplored parts of Asia is about to be formed at St. Petersburg.

MR. WILLIAM JOLLY, H.M. Inspector, has reprinted the paper he read at the B.A. Glasgow Meeting, on Physical Education and Hygiene in Schools. Kempster and Co., London, are the publishers.

IN the last session of the Berlin Anthropological Society Prof. Virchow presented a communication from Dr. Maclay on the results of his journey through the Malay peninsula. In his zigzag course through the mountainous region he repeatedly encountered savage tribes, displaying many points of resemblance with the Nigritos of the Philippine Islands. Two very interesting physical peculiarities of these savages attracted the traveller's attention. The first was the unusually prominent development of the so-called third eye-lid, a feature by no means uncommon among many families of animals; and the second a remarkable inclination sidewards of the three outer toes. This latter peculiarity has been noticed in several members of the ape family. In the course of his trip Dr. Maclay reached what he regarded as the highest mountain of the peninsula. At its foot he found the most numerous remains of the prehistoric Milanesian inhabitants, and encountered the dreaded "Bru," an ape above the human size. His accounts possess a special interest, as they supply the first accurate description of what are probably the only continental representatives of the insular tribes of the Malay Archipelago. Prof. Virchow exhibited also a bronze three-wheel vehicle, excavated near the River Spree, which was ornamented with oxen heads and birds. Among a large number of anthropological objects shown to the Society were a collection of outlines of the feet of negroes on the Loango coast, showing in the most striking manner, by comparison, with the feet of Europeans, the crippling effects of modern costume.

THE South African Exhibition is to be opened at Cape Town on March 15, 1877. We believe that Messrs. R. S. Newall and Co., the well-known lightning-conductor manufacturers, have received the contract for supplying their copper-rope lightning-conductors to the buildings.

A MEETING was recently held in Birmingham of the Council n conection with the projected aquarium for that town. We are glad to see that the arrangements for carrying the scheme into execution are well forward, and a Committee was appointed at he meeting to make all necessary preliminary arrangements. The proposed plan of the aquarium seems to us all that could be esired, and we are glad to see that Mr. Hughes, and other peakers at the above meeting, showed a laudable desire to make he institution serve important educational purposes; we hope, t least, that it will not degenerate into a second-rate music-hall nd miscellaneous rendezvous.

THE French government established many years ago at Athens a school to which pupils are sent yearly at its expense, o study, *in situ*, Greek archæology. M. Jules Simon, when Minister of Public Instruction, established a similar school at Rome, for Italian archæology. Both have been highly successful. The number of works sent to France by them has been so reat that it was stated at the last sitting of the Academy des nscriptions et Belles Lettres, that M. Waddington has determined to issue a special periodical to be called *Annals of Archæology* in order to publish the contributions of the Fellows of the chools and of other French archæologists.

A CORRESPONDENT writes that on Wednesday, about ten minutes to 5 P.M., while at Blackwater, near Yorktown, Hants, he uddenly saw, not sixty yards off, what appeared to be a small all of fire falling from the heavens. It was of a pale yellow colour at first, changing to a lovely bluish green; then, as it pproached nearer to the earth, it became brilliant red, with a tail of fire of the colour already mentioned; and finally, when bout a yard from the ground, it seemed to go out. There was no explosion, no hissing sound. There were thin clouds in the ky at the time, but no wind; and very few stars had come out. t shortly became too dark to ascertain if any body had actually fallen, or if the exploding carbon, or whatever it may have been, ad left any mark on the grass, which was partly under water. Several friends had noticed an aërolite proceeding from north to south in the direction of our correspondent's post, about the time when he saw the fire-ball fall.

THE intensity, colour, and polarisation of the diffuse light of the sky in different parts has recently been a subject of study by M. Wild, of the St. Petersburg Academy, who has endeavoured to measure it with a somewhat complicated instrument devised y him and named a "uranophotometer." Referring to the Academy's *Bulletin* for the account of this instrument, we may ere give briefly the results at which M. Wild has arrived:—

Proceeding from the sun in a vertical circle northwards, it is found that the colour of the light gradually changes from the red end of the spectrum towards the violet, and at about 80° distance from the sun, it reaches about midway between the Fraunhofer lines C and D (corresponding to a wave-length of 0·000628 mm.); from there on to the horizon the colour gradually goes back towards the red end of the spectrum. Thus, in St. Petersburg at the time of equinox, the sun having about 60° zenith distance, the colour tone of the diffuse light at 80° angular distance (in a vertical circle) is mostly pure blue, and passes on either side into green. 2. The saturation of the colour appears to reach its maximum at 90° distance from the sun; where also the degree of polarisation is a maximum. On either side of this maximum the degree both of polarisation and of saturation of colour decreases pretty regularly. 3. The intensity of the diffuse reflected light of the sky appears, on the other hand, to be at its least at about 80° distance from the sun, and from there it increases less quickly towards the horizon than towards the sun. Thus, while at 140° distance from the sun the intensity is about five times greater than at 80°, at 20° distance it is over seven times greater. Southwards from the sun the intensity is considerably greater than northwards for the same distance. Thus, at 20° distance southwards it is nearly twice as great as the same distance northwards. These researches are being further prosecuted by the author.

THE "photography of tones" has been accomplished by Dr. Stein in a way which he describes in *Poggendorff's Annalen* (No. 9, 1876). One variety of his method consists in fixing a tuning-fork horizontally with its branches in vertical planes; there is a hole bored through the upper branch and a horizontal beam of light of somewhat larger section than the hole is directed on this from a heliostat. Part of the beam passes through to a sensitised plate in a case, which plate is made to move rapidly in a horizontal direction by means of a spring, or the like. Thus the luminous circle (on the plate) which, when the fork is vibrated and the plate at rest, gives a vertical line, gives a horizontal sinuous line when the plate is put in motion. The rate of motion of the plate being fixed, there will be a different number of undulations in a given space for each fork of different pitch. The curve has some interesting features; thus, it is much brighter at the bends than at the intermediate parts, the motion having been slower at the points of turning. The gradual retardation and acceleration are clearly shown. Dr. Stein finds it possible to photograph all ordinary musical tones, and even those vibrations which are above the upper limit of audition. He applies his method to strings also; fixing on these, with light supports, small square discs of blackened mica with a hole for admission of the light. Several cords in a row may have their periods photographed together on the same plate, the mica discs rising one above another.

THE additions to the Zoological Society's Gardens during the past week include a Sykes's Monkey (*Cercopithecus albogularis*) from West Africa, presented by Mr. R. Payne; a Vervet Monkey (*Cercopithecus lalandii*) from South Africa, presented by Mr. Thos. Mash; a Rhesus Monkey (*Macacus erythræus*) from India, presented by Mr. J. H. Ivory; a Hoffmann's Sloth (*Cholopus hoffmanni*) from Panama, presented by Mr. L. R. Dickinson; a Silver-backed Fox (*Canis chama*) from South Africa, presented by Mr. Richard Ladd; a Common Paradoxure (*Paradoxurus typus*) from Bengal, presented by Dr. J. B. Wilson; a Black-headed Gull (*Larus ridibundus*), European, presented by Mr. James Smart; two Jardine's Parrots (*Pœocephalus gulielmi*) from West Africa, two Indian Robins (*Geocichla citrina*), two Red-crowned Jay Thrushes (*Garrulax ruficeps*), a Horsfield's Mountain Thrush (*Mycophoneus horsfieldi*) from India, purchased; a Red Coati (*Nasua nasica*) from South America, seven Double-spurred Francolines (*Francolinus bicalcaratus*) from West Africa, deposited.

SCIENTIFIC SERIALS

Memorie della Società degli Spettroscopisti Italiani, for September, 1876, contains a paper on the absorption spectrum of the colouring matters of several molluscs, by Antonio and Giovanni De-Negri. The authors show that the colouring matter of the *Elysia viridis* gives the same absorption spectrum as chlorophyll, and that the colouring matter of other molluscs is identical vegetable colouring matters, or their derivatives.—A table of the solar spots and faculæ observed at Palermo in August and September. On at least half the days there was an absence of spots. The spectroscopic image of the sun's limb as seen at Rome in January and February, 1875, accompanies this number.—Prof. Serpieri continues his paper on the observations of the zodiacal light, by G. Jones.

October.—This number contains a very quaint drawing of the sun taken from Kircher's "Mundus Subterraneus." It represents a spherical body covered with flames, bright spots of light, and puffs of smoke giving the appearance somewhat of facula, spots, and prominences.—Spectroscopic and direct observations of the sun made at Palermo in August and September last, by Prof. Tacchini. He remarks that the height of the chromosphore, about 12″, seems greater than is usual at the minimum sunspot period where hitherto a diminution has been noticed, the eruptions were smaller in number. Prof. Serpieri continues his paper in this number.

Poggendorff's Annalen der Physik und Chemie, No. 10, 1876.—On the heat conduction of gases and vapours, and the dependence of their specific heat on temperature, by M. Winkelmann.—On the absolute changes of phase in reflection of light, and on the theory of reflection, by M. Wernicke.—The electric conductivity of chlorhydric, bromhydric, and iodhydric acid, and of sulphuric, phosphoric, oxalic, pyrotartaric, and acetic acid in aqueous solutions, by M. Kohlrausch.—On the transverse vibrations of liquid films, by M. Melde.—On the photography of the less refrangible parts of the solar spectrum, by MM. Vogel and Lohse.—On the number of electric materials, by M. Neumann.—On anhydride sulphuric acid and a new hydrate of sulphuric acid, by M. Weber.—Remarks on M. v. Oettingen's paper on temperature and adiabata, by M. Clausius.—On the smallest deflection in the prism, by M. Lommel.—On the momentary illumination in observation of light wave streaks, by M. Mach.—On a radiometer experiment, by M. Krüss.—Safety arrangement for hydrogen-making apparatus for avoidance of oxyhydrogen explosions on mixture of the gas, by M. Rosenfeld.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, December 14.—"Note on the Photographic Spectra of Stars." By William Huggins, D.C.L., LL.D., F.R.S.

In the year 1863 Dr. Miller and myself obtained the photograph of the spectrum of Sirius.

"On January 27, 1863, and on March 3 of the same year, when the spectrum of this star (Sirius) was caused to fall upon a sensitive collodion surface, an intense spectrum of the more refrangible part was obtained. From want of accurate adjustment of the focus, or from the motion of the star not being exactly compensated by the clock movement, or from atmospheric tremor, the spectrum, though tolerably defined at the edges, presented no indications of lines. Our other investigations have hitherto prevented us from continuing these experiments further; but we have not abandoned our intention of pursuing them." [1]

I have recently resumed these experiments by the aid of the 18-inch speculum belonging to the Royal Society's telescope in my possession. Considerable delay has arisen from the necessity, for these observations, of a more uniform motion of the driving clock. For this purpose Mr. Howard Grubb has successfully applied to the clock the control of a seconds pendulum in electric connection with a sidereal clock. This system works quite satisfactorily.

The prisms employed are made of Iceland spar, and the lenses of quartz. After an extensive trial of different photographic processes, preference has been given to dry plates.

The apparatus is so arranged that a solar or electric spectrum can be taken on the same plate, for the purpose of comparison, with the spectrum of the star. Spectra have been obtained of Sirius, Vega, Venus, the moon, &c.

I do not purpose in this preliminary notice to describe in detail the arrangements of the special apparatus which has been constructed, nor to offer in their present incomplete state to the Royal Society the results of the experiments. Still I venture to hope that even in this early stage of the inquiry the enlarged copy of the spectrum of Vega (α Lyræ) which accompanies this note, may not be regarded as altogether unworthy of attention.

After exposure to the light of Vega the dry plate was allowed to remain in the instrument until the following morning, when a solar spectrum was taken upon it through the half of the slit which had remained closed when the instrument was directed to the star.

The photograph shows seven strong lines all of them slightly shaded at the sides. The two lines which are least refrangible coincide with two known lines of hydrogen in the solar spectrum.

It is expected, by means of an apparatus now in the course of construction, to obtain also any finer line which may be present in the spectrum of this star, as well as to extend the photographic method to stars which are less bright.

I need not now refer to the many important questions in connection with which photographic observations of stars may be of value.

Anthropological Institute, December 11.—Col. Lane-Fox, president, in the chair.—The following new members were announced:—Rev. A. H. Sayce, G. Tippets, and T. F. Peacock. The following paper, by H. H. Howorth, was read:—On the ethnology of the Germans; Part I., The Saxons of Lower Saxony. The author contended that the Saxons north of the Elbe were immigrants, and of the same race as those south of that river, and that the Saxons were not indigenous to Hanover or Westphalia, but colonists or invaders. This he proved by the topography of those districts and by the names of men, things, &c. He pointed out also the strong differences between the old Saxons and the Saxons who invaded England. He referred to Spruner's Historical Atlas for the definition of the ancient limits of the Saxon peoples.—In the discussion which followed Mr. Hyde Clarke opposed the author's views, and considered that in these matters we had no better authorities than those heretofore accepted.—A paper on the Javanese, by M. Kiehl, who had resided there for some time, was also read, and interesting accounts of the religion, customs, agriculture, &c., of the Javanese were given. Mr. Campbell also spoke on the subject.

Physical Society, December 2.—Prof. G. C. Foster, president, in the chair.—The following candidate was elected a member of the Society:—G. Waldemar von Tunzelmann.—M. Janssen made a brief communication, in French, with reference to a method which he has proposed to the Académie des Sciences for ascertaining whether planets really exist between Mercury and the Sun. After mentioning the importance of photography from an astronomical point of view he explained his reasons for hoping that a series of solar photographs, taken regularly at intervals of about two hours at a number of places on the earth's surface would enable us to determine this question. As it is necessary that such observations be made at several places and in several countries, M. Janssen hopes that other countries besides France, will ere long arrange to have such a series of observations taken, and he considers that in a few years the circumsolar regions would thus be explored with a certainty which could not possibly be attained by any other method. He exhibited some of the original photographs taken in Japan of the transit of Venus, and explained the advantage of placing a grating in the focus of the camera, in order to eliminate distortion.—Mr. Crookes showed the spectrum of a small specimen of chloride of gallium which he had received from its discoverer, M. Lecoq de Boisbaudran. The discovery of this metal is of peculiar interest, as M. Mendelief had previously, from theoretical considerations asserted it to exist, and had also correctly given some of its chemical and physical properties. The most prominent line in the spectrum was a bright line in the blue somewhat more refrangible than that of indium.—Mr. Lodge briefly described a model which he has designed to illustrate flow of electricity, &c., and he showed how similar considerations can be applied in the case of thermo-electric currents. The model in its simplest form consists of an endless cord passing over four pullies, and on one side of the square thus formed it passes through a series of buttons held in their positions by rigid rods or elastic strings, according as they represent layers of a conducting or non-conducting substance. When considered in connection with thermo-electricity, the buttons are assumed to oscillate on the cord, and if they move in one direction with greater velocity than in the other, the cord will tend to move in the former direction. Now at a junction of copper and iron an unsymmetrical oscillation of the molecules must ensue, and the cord, or electric current, will advance when two junctions are at different temperatures. Mr. Lodge showed experimentally that for a given difference of temperature the maximum thermo-electric current is obtained when one of the junctions is at 280° C., and beyond this point the amount of deflection decreases. This fact led Sir W. Thomson to discover the convection of heat by electricity; that is, if we have a circuit composed of copper and iron and one of the junctions be at the above temperature, the current in passing from hot to cold in the iron, or from cold to hot in the copper, absorbs heat. This fact was experimentally illustrated by Mr. Lodge. A strip of tin plate is symmetrically bent so as to nearly touch the two faces of a thermopile and is heated at the bend by steam passing through a brass tube on one side (not end) of the thermopile and kept cold by a current of water on the other side. As the arrangement is symmetrical no current is found to pass through the thermopile, but when a powerful voltaic current passes through the strip of metal, a distinct deflection of the needle is observed in accordance with the above law.

PHILADELPHIA

Academy of Natural Sciences, June.—Prof. Cope's fourth contribution to the history of the existing Cetacea, describes new species of Globiocephalus, Phocæna, and Lagenorhynchus. He also described (July 25) a new fossil genus of Camelidæ, Protolabis, with three upper incisors on each side.

PARIS

Academy of Sciences, December 11.—Vice-Admiral Paris in the chair.—The following papers were read:—Theorems relating to couples of segments making a constant length, taken the one on a tangent of a curve, and the other on a normal of another curve, the two curves being of any order and class, by M. Chasles.—On the composition of glass and crystal among the ancients, by M. Peligot. He proves by quotation and chemical analysis that the glass of the ancients differed importantly in composition from the ordinary glass of to-day; the proportion of lime was much smaller (our good glasses contain 12 to 15 per cent. of their weight of it). Further, no test or analysis proves that the true crystal, the English *flint glass*, was known to the ancients. The honour of its invention belongs to us.—General method of analysis of the tissue of plants, by M. Fremy. He finds the principal tissues of plants, after exhaustion by neutral solvents, to be formed by organic association of (1) cellulo[illegible] bodies (cellulose, paracellulose, metacellulose); (2) vasculose; (3) cutose, (4) pectose, (5) pectate of lime, (6) azotised substances, (7) various mineral matters. He indicates the reagent for each.—On a polymer of oxide of ethylene, by M. Wurtz.—Results obtained on phylloxerised vines by their treatment with sulphocarbonates, manures, and compression of the ground, by M. Marés.—M. de Lesseps presented a report by M. Roudaire on the results of his exploration of the Tunisian Chotts. An extract from an Arabic manuscript found at Nafta shows that the sea at one time reached to that place. M. Roudaire points out the advantages of the new project.—On the laws of impulse (*entraînement*) in plants, by M. Baillon.—A new chapter added to the history of hybrid *Ægilops*, by M. Godron.—Researches on the structure, the modes of formation, and some points relative to the functions of the urns in *Nepenthes distillatoria*, by M. Faivre. The urn is a special formation, *sui generis*, belonging histologically to the foliaceous type, derived from the peduncle, which itself is a continuation of the median nervure of the foliar lamina. The complex liquid of the urns proceeds from the plant itself; and liquid poured into the urns is partly absorbed.—On the caries of bones, by M. Brame.—Researcheson the vitality of the eggs of phylloxera (third communication), by M. Balbiani. The upper limit of temperature, at which the eggs are rendered sterile, is 45°. (The experiments were made with hot water.) The eggs and insects brought out of the ground die quickly on being exposed in a dry place. The eggs by (reason of the chitine of their outer envelope) present much greater resistance to destructive agents than the individuals fully developed; and the germ or embryo is less surely affected by large doses of poisonous vapour acting continuously.—On some processes indicated by Florentinus, for preservation of the vines and for the manufacture of wines, by M. Paulet.—On the geometric construction of the pressures which are borne by several plane elements which cross at the same point of a body, by M. Boussinesq.—Note on the integration of the equation—

$$(xdy - ydx)(a + bx + cy) - dy(a' + b'x + c'y) + dx(a'' + b''x + c''y) = 0,$$

by M. Allégret.—On the spectrum of the new star of the constellation of Cygnus, by M. Cornu. [See separate article.]—Note on the correction of variations in the working of astronomical pendulums arising from differences of atmospheric pressure, by M. Redier. Above the bob is fixed an aneroid barometric case, and a mass connected with the flexible wall of this rises or falls, thus compensating the effects of the pressure.—Note on the theory of the radiometer; extract from letter of Mr. Crookes to M. du Moncel.—Liberation of ammonia observed after rupture of certain bars of steel, by M. Barré. This was verified with red litmus and yellow turmeric paper; which applied to the moistened fracture, changed to blue and brown respectively. Bubbles of gas rose from the moistened surface during a quarter of an hour. The effect is got in Bessemer steels, and in steels obtained from the Siemen's furnace. M. Daubrée remarked that M. Fremy had observed the liberation of ammonia from steels in the cold state in presence of steam. M. Boussingault had discovered nitrogen in all the meteoric irons he had examined, and M. Cloëz had found ammonia in the state of chlorhydrate and carbonate, in the meteorites of Orgueil. He thinks the gaseous bubbles indicated also the presence of a gas less soluble in water than ammonia.—Researches on the urea of the blood, by M. Picard. There are in arterial blood two different substances, both decomposed by Milon's reagent; the one, very destructible, disappears almost completely in the capillaries; the other is fixed, resistant, and exists in venous blood in the same quantity as in arterial (it is probably the urea of the blood)—On the fixed cells of tendons, and their lateral protoplasmic expansions, by M. Renant.—On a dust shower at Boulogne on October 19, and on the mode of formation of earthy rains in general. The dust was mostly of *débris* of various microscopic algæ, with grains of silica and lime; it was probably raised from the beach. He thinks the organic matter in such showers is not, as often supposed, derived from the air.—The height of the quaternary glacier of La Pique, at Bagnères-de-Luchon, by M. Piatte.

DR. SCHLIEMANN'S DISCOVERIES AT MYCENÆ

OF all the archæological discoveries which this nineteenth century has witnessed, that which Dr. Schliemann has just reported from Mycenæ will certainly be regarded as among the most important. Indeed, as throwing a light on those early days of Greece, the glories of which are reflected in the Homeric poems, it will stand pre-eminent, and cast even the researches made by the same ardent explorer at Hissarlik into the shade. There was in that case always some degree of uncertainty, and even his most sincere admirers and sympathisers could not but feel that among the successively disinterred cities it was doubtful which, if indeed any, was the Troy of the Iliad, and whether "the treasure of Priam" was in reality that of the unburied father of Hector.

At Mycenæ, on the contrary, the claim of the ruins which bear that name to be regarded as the representatives of the ancient city founded by Perseus, the massive walls of which were built by the Cyclopes, appears to be indisputable. It is true that Strabo relates that not a vestige of the town had survived to his time, but the account of Pausanias fully identifies the spot where modern geographers place Mycenæ as having been in his days the traditional site of the city.

"In returning to Tretus, on the way to Argos, the ruins of Mycenæ are," he says, "seen on the left, nor is there anything recorded of greater antiquity in the whole of Argolis. When Inachus was king he called the river which flows by after his name, and consecrated it to Juno. In the ruins of Mycenæ is the fountain called Perseia. There are also the underground buildings of Atreus and his sons, in which were kept their treasures. There is, too, the tomb of Atreus and of all those whom Ægistheus slew at the banquet after their return with Agamemnon from Troy. As to the tomb of Cassandra, it is disputed by the Lacedæmonians who live about Amychi. But there is the tomb of Atreus himself and of the charioteer Eurymedon, and that in which Teledamus and Pelops lie together (who were the twin sons of Cassandra, and were slaughtered as infants by Ægistheus at their parents' tomb), and the grave of Electra. But Clytemnestra and Ægistheus were buried a little without the walls as they were not thought worthy to be interred within, where Agamemnon himself, and those who were slain with him, lie."

Such was the legend 1,700 years ago, and making all allowance for the reconstruction of history or legend to which local guides are so prone, there is enough to show that a strong tradition remained upon the spot of an early race of kings whose deeds were famous in the then remote days when the Iliad was composed.

Even now the gate with the lions still stands in the Cyclopean walls, the subterranean buildings and various sepulchres still exist, and the tradition of the treasures of Atreus and his sons appears not to have been without a good foundation. Who were the occupants of the tombs now rifled by Dr. Schliemann must of course be conjectured, but he seems to have brought to light more than one of the kings of the golden city, more than one βασιλῆα πολύχρυσοιο Μυκήνης.

Until we receive photographs of the various objects discovered in the tombs it is idle to speculate upon their forms, which are of course but vaguely described in a hurried account such as that furnished to the *Times* by Dr. Schliemann. Though many of them appear to be novel in character and the general contents of the graves rich beyond all comparison, yet the results of the excavations do not as yet appear to be at all out of harmony with what might have been predicated of the contents of a royal tomb belonging to what prehistoric archæologists would term the close of the Bronze period of Greece—a country where notoriously much allowance must be made for Egyptian influences. The bronze knife, the curious bronze dagger, the bronze swords and lances, the former having scabbards ornamented with gold, the gold-covered buttons, which from the description would seem to be not unlike those found by Sir R. Colt Home in some of our Wiltshire barrows, the long flakes or knives of obsidian, the style of ornamentation of the gold with impressed circles and spiral lines, are all in keeping with such a period. But though in general harmony with what might have been expected, there are, as already observed, also important and special features of novelty in the discovery.

The unprecedented abundance of the gold ornaments, the masks, the great diadems—which possibly may throw some light on the Scandinavian bronze ornaments which go by that name, and also on the Irish gold "minds" and the golden crosses in the form of laurel leaves—the silver sceptres with the crystal balls, the engraved gems, the vases, the great gold pin with the female figure crowned with flowers—possibly the Juno Antheia worshipped in the city of Argos—in fact the whole find will attract the attention of both classical and prehistoric antiquaries.

The pottery discovered appears also to be of peculiar fabric and material, and will no doubt contribute much to our knowledge of ancient fictile art. As all the originals will go to enrich the already important Museum of National Antiquities at Athens, it will be mainly from photographs and drawings that these wonderful objects will be known in this country. Let us in passing express a hope that the photographic and artistic representations of the Mycenæ treasure may be more satisfactory than those which constitute Dr. Schliemann's Hissarlik Album.

With regard to the antiquity to be assigned to these interments, it will be well to bear in mind that they lay at a considerable depth below the slabs first discovered by Dr. Schliemann, the ground beneath which he originally regarded as virgin and undisturbed; that above these slabs lay a great thickness of *débris*, probably accumulated at a time when the city was inhabited, and yet that Mycenæ was destroyed by the Dorians of Argos, about B.C. 468, at a period so early in Greek history that no authenticated coins of the city are known. It seems to have been from the depth at which the interment lay that they escaped the researches of former excavators, including Lord Elgin, upon the site. The reputed tomb of Theseus, which was rifled by Cimon the Athenian the year after the destruction of Mycenæ, must have lain nearer the surface, but the bronze spear and sword which were found in it, and which were brought with the bones in triumph from Scyros to Athens, point to its having belonged to much the same period. The spear of Achilles in the temple of Minerva at Phaselis, and the sword of Memnon in the temple of Æsculapius at Miomedia, were also of bronze, of which metal, as Pausanias observes, all the weapons of the heroic age were made. Had Augustus but known of the buried treasures of Mycenæ when he was collecting the *Arena Heroum* for his museum at Caprea, the researches of Dr. Schliemann might have been in vain.

As it is, he is to be congratulated not only on the extent and importance of his discoveries, but also on his investigation having brought to light those horned Juno idols which he anticipated finding. His theory of some of the owl-like figures from Hissarlik bearing reference to the name of *γλαυκῶπις* Ἀθήνη has met with more ridicule than it deserved, and if the discovery of these horned figures of *βοῶπις πότνια* Ἥρη should be substantiated, Dr. Schliemann will be fairly entitled to claim the victory over his adversaries. Under any circumstances both he and his no less enterprising helpmeet deserve the most cordial thanks of all scholars and antiquaries.

J. E.

PESCHEL'S "RACES OF MAN"

The Races of Man and their Geographical Distribution. From the German of Oscar Peschel. (London: Henry S. King and Co., 1876.)

THIS book appears from the preface to be founded on General A. von Roon's "Ethnology as an Introduction to Political Geography," though it is substantially a new work intended to form a complete manual of ethnology. The actual title is somewhat misleading, as no special prominence is given to problems of geographical distribution, while languages, myths, and mere tribal distinctions, are treated with great and somewhat bewildering detail. The perusal of a work like the present, which, with great labour attempts to bring together in a compact form, all the existing information as to the physical and mental characteristics of the various races of mankind, impresses one painfully with the still chaotic state of the infant science of anthropology. With an overwhelming mass of detail as to secondary and often unimportant characters, we find a frequent want of exact knowledge as to the chief physical and mental characteristics of the several races and sub-races.

Language, myths, habits, clothing, ornaments, weapons, are described in detail, while we are left without any sufficient information as to the stature, bodily proportions, features, and broad mental characteristics of many important groups of men. The reason is obvious. The former class of facts can be readily obtained by passing travellers; while the latter require the systematic observation of an intelligent resident and more or less skilled anthropologist, and can only be arrived at by means of careful measurements and long-continued observations. It is not sufficiently considered that in almost every part of the world there is more or less intermixture of races, brought about by various causes—as slavery, war, trade, and accidental migrations. Hence in many cases the passing traveller is altogether deceived as to the characters of the race, and any observations he may make are of little value. It is only by a long residence among a people, by travelling through the whole district they inhabit, and by a more or less accurate knowledge of the surrounding tribes with whom they may be intermixed, that the observer is enabled to disentangle the complexities they present, and determine with some approach to accuracy the limits of variation of the pure or typical race. Unfortunately this has yet been done in comparatively few cases; but anthropologists are now becoming impressed with its importance, and we may soon hope to obtain a body of trustworthy materials, which may enable us to determine, with more confidence than is yet possible, the characters and the affinities of many of the best marked races of mankind.

We will now give a sketch of the mode in which the subject is dealt with in the present work, and point out some of the more striking merits and defects it possesses. The first and larger portion of the book treats of the various physical and mental characteristics of mankind, the latter portion being devoted to a systematic review of the races and tribal divisions. The introductory chapter treats of man's place in nature, origin, and antiquity; and while adopting the developmental theory as regards animals, argues with more or less force, against the Darwinian theory of the animal origin of man and especially against the influence of sexual selection. The hypothetical continent—Lemuria—is suggested as the most probable birthplace of the human race, and it is explained that this locality is "far more orthodox than it might at the first glance appear, for we here find ourselves in the neighbourhood of the four enigmatic rivers of the scriptural Eden—the Nile, the Euphrates, the Tigris, and the Indus." The unity of mankind as constituting a single *species*, is strongly urged, while the evidences of his antiquity are briefly but forcibly set forth. We are glad to see due weight given to Horner's borings in the Nile valley, which we have always thought have been unduly depreciated. It is well remarked that the suggestion of the piece of pottery found at a depth of 39 feet having fallen into an ancient well or tank, is altogether groundless, because this is only one out of a large number of fragments of bricks and pottery found at various depths over an extensive area, and there is certainly no reason why the one found at the greatest depth should have fallen into a well rather than any or all of the others. It seems not to have been considered, by those who have advanced this view, that a well at Memphis, close to the Nile, could not have been very deep, and that if it had been it would probably have been in use for many centuries, and would have become the receptacle, not of a solitary fragment of pottery, but of a whole collection of utensils, ornaments, and domestic implements, such as invariably fall into wells in the course of time. Moreover, a well 40 feet deep in the soft alluvium of the Nile must certainly have been lined with stone or brickwork, and have been protected at the top by some inclosure solid enough to have resisted the muddy inundation water, and it would almost certainly have been covered over to keep out sand and dust in the dry season. It would therefore be almost impossible to bore on the site of an ancient well without knowing it; so that no more hasty and unsound suggestion to avoid a supposed difficulty was ever made than this "well theory," and yet, strange to say, it has been almost universally adopted as fatal to all calculations founded on these careful borings. It seems to be thought that although we must have facts to establish a theory, we need only have suppositions to overthrow them.

The next chapter—on the Physical Characters of the Races of Mankind—treats pretty fully of the brain and cranium, and also of the hair, but far less satisfactorily (owing to absence of material) of other physical characters; and the conclusion arrived at is "that neither the shape of the skull nor any other portion of the skeleton has afforded distinguishing marks of the human races; that the colour of the skin likewise displays only various gradations of darkness, and that the hair alone comes to the aid of our systematic attempts, and even this not always, and never with sufficient decisiveness."

The next chapter treats of Linguistic Characters. While speaking favourably of the imitative and interjectional theory of language, its powers are unnecessarily "limited to events connected with the production of sounds, for no such representation is possible of that which is perceived by sight or the sense of touch." It has, however, been often shown that roots derived from sounds or emotions may soon be applied by metaphor, analogy, or contrast, to a wide variety of meanings; and it may perhaps be something more than a coincidence, that the languages which possess the smallest number of primitive sounds—the Polynesian—belong to an area where from the total absence of mammalia and paucity of birds and insects the variety of natural sounds is extremely small. The chapter which treats of Social and Religious Development is very voluminous, occupying considerably more than one-third of the whole work, while more than seventy pages are occupied with an account of the various religions, a large part of which is modern history and has the smallest possible connection with ethnology. This chapter is full of facts intermingled with a good deal of more or less doubtful philosophy. We may call attention, however, to the view that cannibalism is not a character of the lowest state of savagery, but is "more frequently encountered exactly among those nations and groups of nations which are distinguished from their neighbours by their abilities and more mature social condition." The ancient Mexicans, the Fijians, the Battas of Sumatra, as well as the Fans, Niamniams, and Monbuttos of Central Africa are adduced as examples, and as likewise proving that it is not the absence of animal food that has led to the formation of the habit. On the question of the first discovery of fire there is much wasted argument, founded on the erroneous assumption that to obtain fire by friction is a most laborious operation and always requires the combined labour of two persons (p. 143). On the contrary, either by the hand-drill or by rubbing it is effected with great rapidity by one individual, and there is really no reason why it might not have been independently discovered in different parts of the world.

One of the best passages in this part of the work is that which treats of the influence of commerce on the migrations of nations (pp. 210–214). Humboldt has remarked that had not Columbus altered his course a few days before sighting America he would have landed in Florida, and the Spaniards would have peopled the United States instead of Central America, and the New World would now have had quite different ethnographical features. This was a very crude and unphilosophical remark of Humboldt's, for, as our author shows, the portion of America to be colonised by Spaniards was almost wholly determined by the presence of the precious metals. Wherever these were not found they marked on their charts as "worthless territories," and had they first discovered the present United States they would certainly have at once abandoned them. Agricultural colonies were not possible at that early period, and the first settlements of the French and English literally perished of starvation. Tobacco as a valuable article of commerce first made Virginia flourish. The demand for codfish in France caused Canada to become a French colony. The Russians have settled wherever furs were obtainable. Spices caused the Portuguese and Dutch to settle in the far East, while in modern times the attraction of gold has led to the peopling of California with Anglo-Americans. This interesting discussion is summed up with the remark:—

> "We thus see how much we owe to the rare and precious products of the animal, vegetable, and mineral kingdoms, as the means by which human culture was spread, and as the baits which attracted national migrations, and we perceive that the regions which were fortunate enough to possess such treasures were the first to be drawn into the sphere of a higher culture; the direction in which civilisation has moved has frequently been prescribed by this influence."

In the last part of the work, devoted to a detailed exposition of the races of mankind, we have a somewhat peculiar primary division into seven groups. The first includes the inhabitants of Tasmania and Australia; the second, the Papuans of New Guinea and the adjacent islands; the third, the Mongoloid nations, including the Malayo-Polynesians and native Americans; the fourth, the Dravida of Western India; the fifth, the Hottentots and Bushmen; the sixth, the Negroes; and the last, the Mediterranean nations, answering to the Caucasians or Indo-Europeans of other ethnologists. The Tasmanians are said to have "exactly resembled the Australians in all points, except that the growth of the hair was more Papuan in character." The supposed resemblance of Australians to the aboriginal inhabitants of Central India is set aside as entirely without foundation, while they are said to be decidedly nearest of kin to the Papuans. These latter are associated with the Negritos and the Andaman Islanders. Notwithstanding that a wide-spread relationship between Papuan and Polynesian languages is affirmed (p. 342), yet the Polynesians are associated with the Malays as a Mongoloid sub-race, the Malayo-Polynesians, an association which the present writer holds to be radically erroneous. The American tribes are treated as a single homogeneous group which entered the continent from the north-west, and little weight is given to the great differences of mental and physical character which exist and which are certainly greater than can be explained by a comparatively modern origin from a single stock. Very much yet remains to be done in determining the successive waves of migration which have flowed into the American continent, and we hardly think our author is justified in ranking the American aborigines as far higher than the negroes, on the ground that the former have, *quite independently*, reached a much higher civilisation. Throughout all this portion of the book a vast mass of information is given as to the tribal divisions, habits, languages, and migrations of the several groups; but these details often obscure those broader features of physical and mental peculiarity which are of most importance in arriving at correct conclusions as to the primary divisions of mankind and the true affinities of the various races.

It is impossible here to notice the many interesting questions which arise as we peruse the mass of facts and opinions set forth in such a work as this. Although unequal in treatment, and in many respects imperfect, it exhibits much labour and research, and treats in more or less detail every branch of the great and rapidly-developing science of anthropology; and it forms on the whole as good a manual of the subject as we are at present likely to obtain from a single author. It is to be hoped that when another English edition is required some well-instructed anthropologist may revise and edit the work, so as to modify (by means of footnotes or otherwise) the unusual treatment of many questions of which our author gives a more or less one-sided exposition.[1]

ALFRED R. WALLACE

OUR BOOK SHELF

Ostriches and Ostrich Farming. By Messrs. De Mosenthal and Harting. 8vo. pp. i.-xxii., 1-246. (London: Trübner and Co., 1876.)

IF ornithologists have regretted the apparent retirement of Mr. Harting for the last few years from the field of scientific research, they will find on consulting the present volume that his devotion during that time to popular science has not impaired his powers, but has perhaps tended to increase the gift which he always possessed in a high degree, of being able to present to his readers the details of science in interesting and attractive language. We have been induced to make the above remarks, inasmuch as no one would suspect that under the above title is comprised a very complete monograph of the *Struthionidæ* from the pen of Mr. Harting, but such is really the case, for, out of a volume of some 250 pages, three-fourths are occupied with the history of the ostrich and its kindred. This portion of the work is entirely written by Mr. Harting, and, like everything he undertakes, is executed with thorough conscientiousness. The true Ostriches (*Struthio*), the Rheas (*Rhea*), the Emu (*Dromæus*), the Cassowaries (*Casuarius*), and the *Apteryges* are all passed in review, and a complete monographic account given of each; the history of the ostrich and its distribution in times past and present being very exhaustively compiled. We can heartily commend the illustrations in this volume, very good full-page drawings of the principal Struthious forms, having been designed by Mr. T. W. Wood, while the Zoological Society has allowed the woodcuts which have illustrated Dr. Sclater's various memoirs on the *Struthionidæ* to be utilised, so that a very complete monograph of these birds is the result.

Mr. De Mosenthal's portion of the work is confined to the practical "Ostrich Farming," and seems to be extremely well worked out, giving a history of the development of the pursuit from its first commencement. The author's personal experience has been confined to South Africa, where ostrich-farming has acquired its chief importance, but the statistics of the exportation of feathers from the other parts of Africa show that at present the greatest trade is done through Egypt, the annual value of the exports from this country being 250,000*l.* The Cape comes next with exports to the value of 20,000*l.* less, while from Barbary the value is 100,000*l.* annually, from Mogador 20,000*l.*, and Senegal 3,000*l.* The whole of the process of the artificial incubation of the eggs is described with minuteness, and altogether the contribution is most entertaining and instructive. The volume concludes with an appendix giving consular and other reports, all of which supply important statistics and interesting historical matter bearing on the subject.

Die Darwin'sche Theorien und ihre Stellung zur Philosophie, Religion und Moral. Von Rudolf Schmid, Stadtpfarrer in Friedrichshafen. (Stuttgart, 1876.)

A GLANCE through this book will not satisfy the reader that the great problems of modern thought are to be settled even by the well-meant essays of a well-read pastor. It is one of the "reconciliations" of science and religion, so common in England, but less so in Germany, where people are in general unwilling to check views on scientific questions by their relation to theology. The author impresses on his readers that the theory of universal law is compatible with the Christian doctrine of miracles, and that the Darwinian hypothesis of development may really receive strong support from the doctrine of human development in a future state. But his arguments prove little or nothing one way or the other. Next, turning to the Creation, we find him placidly remarking that the order of its stages is given differently in Genesis and again in Job, his inference being that neither order is "binding on us." The six days, in his opinion, are not natural days, nor are they geological periods, for neither would this fit with the geological evidence; he therefore concludes that they are "divine days," whatever that may mean. Such reading ought to suggest to religious minds the serious question whether disbelief can do so much harm as the habit of perverting and mystifying belief. We may hope that when theologians have become more familiar with the theory of evolution as manifested in the development of religious ideas themselves, their reconciliation of man's religious tendencies with his scientific knowledge may be placed on a higher basis than in such attempts as this, of which the weakness is only made more conspicuous by its good intention.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*]

Sea Fisheries

As an enthusiastic amateur sea-fisher some twenty years ago on the Canadian coast of what the Americans call the "herring-pond," perhaps you will allow me to make a remark or two on Mr. Holdsworth's letter in NATURE, vol. xv., p. 135. Long absence from that happy hunting-ground has not beclouded my memory, for I often in imagination fight again my battles with halibut and skate, lobster and cod, and the words "sea fisheries" have not altogether lost their charm; but I confess I wholly overlooked Prof. Newton's interesting letter on the subject, and turned back the file of NATURE and read the letter in connection with Mr. Holdsworth's. The theory of the former appears to me to be the correct one; the Atlantic sea fishery is being gradually played out.

---

[1] The translation is from the second edition, yet there are a considerable number of errors and oversights, some of which it may be useful to point out. First we must notice that the copious table of contents is rendered quite useless by the absence of a single reference to the pages at which the several chapters and sections begin or end. Among errors of fact we notice (at p. 2) that the Hylobates is said to "stand far nearer to man than the other three highest apes;" at p. 20, that the Dutch are not acclimatised in the East; at p. 117, that the Malays always use the word *stone* in counting as "three *stones* chickens," the fact being that *stone* or *seed* is used for inanimate objects only, *tail* for living things, as "three *tails* chickens," &c.; at p. 204 "the Sunda, Banda, and Molucca Islands," are said to have formerly bound together Asia and Australia, but by subsidence have become "groups of islands in a shallow sea;" and again, at p. 205, the Gulf of Mexico and Caribbean Seas are both said to be *shallow*, and to show a former connection with the continent; p. 343, Papuans are said to smelt iron ore; this I think is quite erroneous, though on the coast they work iron brought them by the Malays and traders; at p. 344 the Papuans are said to cultivate *trees*, and to possess "only seedless varieties of the bread fruit," the exact contrary being the fact; at p. 413 guinea-fowls are put as natives of the New World, and "prairie dogs" as domestic animals; at p. 414 the "ounce" is put for the "jaguar;" at p. 423 "(*Crax*) guinea-fowls," are said to be bred for food. Of oversights or mistranslations we notice at p. 85, lines 10-11, figures which are quite unintelligible; p. 366, line 1, "allows too long" is a bad translation; p. 368, line 2, "outbreak of the pestilence" refers to the nutmeg disease.—A. R. W.

I doubt whether we can anywhere along its extensive coast now meet with "shoals" of mackerel or "schools" of herring several miles in breadth, forming a mass of so compact a nature that small vessels had almost as much difficulty in getting through them as Sir George Nares had in getting through the so-called palæocrystic ice, or hear of single hauls of 1,000 barrels! And yet such was possible not twenty-five years ago.

The great mischief is done, certainly in America, by trawling. This must be evident if one will but consider the *modus operandi*, by which the female fish are captured just before they have deposited their spawn, a few thousand fish so taken representing the non-existence of many millions. The subject has received the most serious attention of the Canadian Government, and has by it been brought under the notice of the United States and French authorities.

Mr. Holdsworth appears very much amused to find that Prof. Newton has discovered a use for dogfish over and above his own instance, in which it served as "salmon" for the Preston weavers. But as we have never heard that the fishermen of Morecambe Bay were charged with feloniously administering a poison to the said weavers, we must conclude that dogfish is a wholesome, but perhaps not a toothsome, article of food.

Mr. Holdsworth says that with this exception he has never heard of a case in which "the hated dogfish was not knocked on the head and thrown overboard whenever there was a chance of so doing." I can tell him one. Along the American coast the dogfish is certainly knocked on the head, but the fishermen there know its value too well to throw it overboard; they keep it, and it yields an oil; and of the many millions of gallons of "fish-oil" in the returns, "dog-oil" forms no inconsiderable portion.

There can be no doubt that the American fishermen, if they had had their say in creation, would have vetoed dogfish; but as they had not, they came to the conclusion that there was doubtless some wise purpose even in that creature: a thorn in the flesh to try their tempers and their nets, but one which they forced to bear fruit.

If it is true that the nets of the Donegal fishermen in 1875 were constantly full of dogfish, and they driven to their wits' end, I hope some Donegal reader of NATURE will kindly read them this letter; it may be the means of opening up a glorious future for Ireland. Perhaps too some Lancashire reader will give the Morecambe Bay fishermen a hint, in case the Blackburn weaver should hereafter have a surfeit of "salmon," and those practical jokers' occupation be gone.

May I in conclusion be allowed to dissent from Prof. Baird's plural of "alewife?" He calls it "alewives." There is nothing of the meaning of *wife* in the word. This species of herring, which usually goes by the name of *gaspereau*, is also called *alewife*, which is a corruption of the Indian word for a fish, *aloof*. The plural, I think, should be "alewifes." B. G. JENKINS

Dulwich, December 18

Sense of Hearing in Birds and Insects

I do not know whether ornithologists are acquainted with the peculiar manner in which curlews frequently obtain their food on sandy flats which have been left bare by the tide. The birds force their long bills into the wet sand as far as the nostrils, and then again withdraw it, leaving a small hole, which, when probed, is found to be only just large enough to have taken in the bill. The animal, therefore, can only have made a single prolonged push without adding any lateral or exploring movements of the bill, as birds which feed in mud may be observed to do. Now it cannot be supposed that curlews adopt this mode of feeding without obtaining from it some degree of profit. Neither can it be supposed that they make their thrusts into the sand at random; for, their bills being so pointed and slender, the birds would usually require to make a vast number of ineffectual thrusts before they happened to hit upon a worm or other edible object. The question therefore is, How do the birds know the precise spots where their victims lie buried in the sand? That this knowledge is not derived by sight I am quite sure, for I have repeatedly observed innumerable curlew marks of the kind described occurring on tracts of sand which, in virtue of their high level, presented a perfectly smooth and uniform surface. I can therefore only suppose that the birds are guided in their probings by their sense of hearing. Doubtless it is difficult to believe that this sense is so delicate and precise as to enable the curlew to perceive so exceedingly slight a sound as that which must be caused by the movement, say, of a small worm at a distance of ten or twelve inches from the surface of the sand, and at the same time to localise the exact spot beneath the surface from which so slight a sound proceeds. I cannot see, however, that any other explanation is open, and perhaps the one now offered may not seem so incredible if we remember the case of the thrush. No one, I think, can observe this bird feeding and doubt that it finds its worms and grubs almost exclusively by the sense of hearing. And if the distance which it runs between successive pauses for listening represents—as we cannot but suppose it must—the diameter of the circle within which this bird is able to hear the movements of a worm, I think that the hypothesis I have just advanced with regard to the curlew ceases to be improbable.

It seems worth while to add a few words with respect to the sense of hearing in insects. So far as I am aware, the occurrence of such a sense in this class has never been actually proved, although on *à priori* grounds there can scarcely be any doubt concerning the fact of some insects being able to hear; seeing that in so many species stridulation and other sounds are made during the season of courtship. In the case of moths, however, I believe that sounds are never emitted—except, of course, the death's-head. It therefore becomes interesting to observe that an auditory sense is certainly present in these insects. Several kinds of moth have the habit of gently, though very rapidly, vibrating their wings, while they themselves are at rest on a flower or other surface. If, while this vibrating movement of the wings is going on, the observer makes a sudden shrill note with a violin or fife, &c., the vibrating movement immediately ceases, and sometimes the whole body of the insect gives a sudden start. These marked indications of hearing I found invariably to follow a note with a high pitch, but not a note with a low one. GEORGE J. ROMANES

"Towering" of Birds

I HAVE read Mr. Romanes' communication on the "towering" of grouse and partridges with much interest. As he requests further information, may I be permitted to contribute the following:—I once observed a pheasant which, after being shot, flew apparently untouched for about one hundred yards, then towered ten or fifteen yards, and fell dead. As a rule birds that have towered are picked up dead, as Mr. Romanes states; but such is not invariably the case. A correspondence took place in the *Field* some weeks since in answer to the question: "Do towered birds *ever* rise again," and several replies were elicited in the affirmative. The conclusion warranted by that correspondence seemed to be that towering arises from at least two distinct kinds of injury. In the first, the common form, the bird is struck in the *back*, and is always found precisely where marked down. It seems to me that in this kind of towering the *perpendicular* flight may be attributed to a cause perhaps other than, or at all events additional to, *pulmonary* hæmorrhage. I consider that hæmorrhage is a necessary factor, and Mr. Romanes makes but a very strong case in favour of its being into the lungs. That the movements of the wings are convulsive, and the explanation of the towering, I am not inclined to dispute, but I think it has yet to be proved that the convulsive flapping of wings (the directing power of the brain being in abeyance) always produces perpendicular and never merely erratic flight. Every towering bird acts in a precisely similar way. Are we to take it for granted that in asphyxia it is only certain sets of muscles, and these always in the same and to an equal degree, that are spasmodically affected? I have noticed that a towering bird very often has his legs hanging straight down (I do not allude to those cases where they are palpably mutilated), and it strikes me as being likely that paralysis of the legs and lower part of the back may have something to do with the flight being upward. A man who has paraplegia always complains that he cannot move his legs because they are *so heavy*. This sensation would doubtless be felt by a bird paralysed behind, and this, in addition to the loss of its steering apparatus and the co-operating contractions of the posterior muscles, would produce a loss of balance with much the same effect as though the after parts had really become disproportionately heavy. I have no desire to be dogmatic, but merely offer this as a possible assisting factor in some cases.

In towering from the second kind of injury, the bird can and sometimes does fly away from the place where it fell, and, after retrieving, concordant testimony shows lesion in the neighbourhood of the *eyes*, whence blindness has been assumed to be the cause. The fact that this very rarely occurs, perfectly agrees with the objection that the smallness of the head is adverse to the theory of cerebral injury being the invariable cause. It has further been noticed that these birds seldom move until they are touched. Whether, attention having been drawn to this subject, future observers will detect a difference in the towering of birds that may, and those that cannot, rise again, is hard to say, but I hope, in the interests of science, all pertinent observations will be communicated and admitted into the columns of NATURE.

Faringdon, Berks, December 11 J. HOPKINS WALTERS

The Tasmanians

I SEE it stated in NATURE, vol. xiv. p. 242 (which has just reached us), that M. Castelnau, French Consul at Sydney, states in a letter "to the Geographical Society of Paris, read at its last sitting, that the only four Tasmanians living were presented at the last levée held by the Governor of Tasmania."

I cannot imagine how M. Castelnau can have allowed himself to propagate such an error. It is quite true that four Tasmanian aborigines were presented at a governor's levée, but the presentation occurred just ten years ago, and all the four have long since been gathered to their fathers.

In reference to the last paragraph in your note, I regret to say that we really "have seen the last of them." The sole survivor of this singular race, a female, by name Trucanini, died a few months ago at the age of seventy or thereabouts. The "penultimate" aborigine was King Billy, who preceded Trucanini to the grave three years ago. W. W. SPICEY

Hobart Town, October 21

Algoid Swarm-spores

IN a note on algoid swarm spores, published in NATURE, vol. xv. p. 15, reference is made to the new investigations of M. Sachy, who considers the motion and accumulation of spore as due to currents produced by differences of temperature in the water, and not at all to the action of the light causing the living swarm-spores to move. I do not know the experiments by which this result has been reached; but the following seems to me a confirmation of the new theory.

At a distance of about 5 feet from the window of my room is placed a cylindrical glass vessel of 1 foot in diameter, and containing only some sphagna and microscopical crustacea. This aquarium has been kept unshaken for four years.

Now a great quantity of green alga is collected on the side opposite to the window, while the side turned towards the light is covered with a considerable number of little particles of an amorphous matter, arranged in pretty regular cloudy forms, containing nothing but *débris* of plants or animals, and a few desmidiæ.

These particles, which cannot be considered as *living matter*, arise from the light mud which covers the sand at the bottom of the aquarium. The right and left sides of the vessel remain quite clean.

I should much like to know if any of your readers have observed similar facts. E. RODIER

29, rue Saubat, Bordeaux, December 17

Meteor

I SAW the meteor spoken of by your correspondent (*ante*, p. 170) at Blackwater on Wednesday the 13th inst. at 4.45 P.M. as I was passing down St. James's Square. It was apparently of somewhat greater magnitude than the planet Jupiter, and passed from north to south, till it disappeared behind the houses.

Your correspondent will find two notices of the same meteor in the *Times* of the 15th inst. P. L. SCLATER

ON THE RELATION BETWEEN FLOWERS AND INSECTS[1]

THE habit possessed by our honey-bee of feeding itself from flowers, and its corresponding faculty of deciding amongst different species and divining the situation of the honey, is, in the first instance, derived from the common parents of all the Hymenoptera. It probably even comes from such remote ancestors as the leaf-cutting wasp, from them passes to the gall-flies, the ichneumons, and the hunting-wasps, from which latter it goes to the allied species of ants and bees. We may see all these families of Hymenoptera feeding on the honey and pollen of flowers, and manifesting a certain, if not always very obvious, intelligence in choosing the flower to be visited.

The various families of wasps differ amongst each other as to their ingenuity in finding the honey, but it is in the bees that we first arrive at the more complex use of the food, *i.e.*, not merely for the insect itself, but also for its young, combined with such intelligence in its discovery, as proves that the most highly developed form of insect is the one which profits by the honey lying most concealed. The following observations may throw some light on the foregoing statements:—

I come to the conclusion that the Hymenoptera enumerated have a certain degree of intelligence, at least with regard to honey that is in sight, from never having seen leaf-cutting wasps or ichneumons, and still less hunting-wasps or bees, seek honey so long in flowers where it does not exist as is the case with some species of beetles, which feed frequently or exclusively on the nourishment derived from flowers.

However, even very highly-organised insects are at times misled, and Dr. Müller cites one case in which *Melampyrum arvense* was surrounded by a crowd of ichneumons, bees, &c., seeking the honey in vain, the only one which succeeded in obtaining it being *Bombus hortorum*, which has the longest proboscis of all our humble-bees.

It cannot be said either of the leaf-cutting wasps or of the gall-flies that they attain a high degree of intelligence in finding concealed honey, and to these we may add the ichneumons which are frequently found on plants with the honey easily seen (Umbelliferæ, Listera, Ruta, &c.), much more rarely on those where it is partially concealed (Cruciferæ, Spiræa, Salix), and quite as an exception on those in which it is completely hidden (Gypsophila, Malva, Mentha.)

When once a family of Hymenoptera has attained to the point of intelligence of providing food for its young and placing it along with the eggs, we see it develop greater dexterity in its search for honey. In comparing, for instance, the statistics of the visits of the leaf-cutting wasp and the hunting-wasp, we find that even the most developed leaf-cutting wasp only attempts to rob those flowers whose simple form renders the honey easy of access. Even those of Bryonia and Reseda seem unattainable by them. On the contrary, we see the hunting-wasps attack not only these, but also flowers specially adapted to the movements of the fossorial Hymenoptera, for example, Echium, the Labiates, and the Papilionaceæ, and also the pendent bells of Symphoricarpus, which only allow ingress to the honey from below. It must be deduced from the above statements that flowers and the insects which visit them are adapted to each other, and have gone through corresponding degrees of development at each period of the world's history. For example, if my view of the origin of the Hymenoptera is correct, there has been a time when species with an ovipositor were the only Hymenoptera; and when only regular, open, turned-up flowers of as low a form as Salix existed, while Reseda, Echium, the Labiates, the Papilionaceæ, &c., &c., have been developed at a later period after the species of Hymenoptera had developed to the point of preparing a place for their young.

We may therefore see how through the transition of hunting-wasps to the habits of bees, and further within the bee-like family, dexterity in acquiring the food has increased. The species perhaps most nearly allied to the ancestors of the bee—Prosopis—is, as to its organisation, on the same footing with the hunting-wasp, and, as to the length of its tongue, is even but little more highly developed. The assiduity with which it visits the flowers, its practice in seeking those where the honey is concealed, its well-established habit of feeding its young entirely on food derived from flowers, all place it above the average of its ancestral species. Even, however, among these ancestral species—the hunting-wasps—are certain kinds whose love for flowers has far surpassed their power of rearing a family, and these, favoured by their large size and length of tongue, have attained still greater dexterity in getting at concealed honey than Prosopis.

---

[1] Abstract of an article in the *Bienen Zeitung* by Dr. H. Müller.

Out of eighty-five visits to flowers by different species, there were of Prosopis :—

On flowers with the honey apparent, 19 = 22·4 per cent.

On flowers with the honey somewhat concealed, but still fairly apparent, 19 = 22·4 per cent.

On flowers with the honey concealed, but easily reached through the formation of the mouth, 28 = 32·9 per cent.

On flowers with the honey entirely concealed, which are specially adapted to the burrowing Hymenoptera, 8 = 9·4 per cent.

On flowers without honey, or at least only having pollen as far as Prosopis is concerned, 11 = 12·9 per cent.

Some of the hunting-wasps appear to show even more intelligence than Prosopis in the search for honey, and this will appear still more forcibly if we leave out the flowers which only yield pollen, when the total result is for the wasps 35·3 per cent., for the Prosopis 48·6 per cent.

The following table will show at a glance how far the hunting-wasps are above the leaf-cutting wasps, how far the former are surpassed by Prosopis, and how far the hunting-wasps, most eager for flowers, again surpass the Prosopis.

	a	*b*	*a*+*b*	*c*	*d*	*c*+*d*	*e*	*f*
Leaf-cutting wasps	69·1	16·3	85·4	13·0	0	13·0	0	1·6
Majority of wasps indifferent to flowers	55·3	17·8	93·1	24·0	1·0	25·0	1·9	—
Principal hunting wasps ...	44·7	19·0	63·7	30·0	4·8	34·8	1·5	—
Prosopis	22·4	22·4	44·8	32·9	9·4	42·3	12·9	—
The wasps most eager for flowers	10·8	23·1	33·9	49·2	16·9	66·1	—	—

If we look down the perpendicular lines of this table from top to bottom we shall see the frequency of the visits to the flowers with the honey apparent (*a*) even if we add the visits to the flowers with the partially seen honey (*a* + *b*) steadily decline, though the visits to the flowers with partially concealed honey (*b*) steadily increase. In still more rapid ratio the frequency of the visits to the honey entirely concealed, increases (*c* + *d*), both in the case of those flowers whose honey is easily attainable through the simple form of the corolla (*c*), and those specially adapted to the burrowing Hymenoptera (*d*).

With regard to the flowers yielding only pollen (*e*), the Prosopis shows a remarkable advance on the other Hymenoptera, probably caused by the great need the young fed from flowers have of the pollen.

The results of a careful series of observations, prolonged over a course of five summers, brings us to the following conclusions :—

1. The Tenthredos stand, as regards the rearing of their young and in their general intelligence, as well as in their capacity of finding and acquiring concealed honey, the lowest of all the Hymenoptera we have considered. They visit flowers with the honey altogether apparent much more frequently than those with the honey wholly or partially concealed, and the latter only in the case of those with a low and simple organisation.

2. The hunting-wasps, which, as has been previously shown, stand decidedly above the Tenthredos, show also a decidedly higher power of finding honey. Even when the most intelligent and flower-loving families are excluded, a high percentage among the hunting-wasps is found visiting flowers with concealed honey, and a lower visiting flowers where the honey is apparent; they even seek some flowers whose formation shows them to be adapted to the fossorial Hymenoptera. All this progress appears still more remarkable when we compare the whole group of Tenthredos with the whole group of hunting-wasps.

3. Prosopis, the least highly-developed bee, and one which does not stand higher than the hunting-wasps, either in general capacity or in care for its young, is yet compelled, through the greater requirements of the latter and their need of pollen, to visit both flowers with concealed honey and flowers which only produce pollen.

4. Certain species of hunting-wasps stand above the Prosopis, both in size and in the length of the proboscis; these, however, only seek food from flowers for themselves, and not for their young.

We may now hope through the following steps to obtain some idea how the honey-bee has acquired its peculiar capacity for finding concealed honey.

All our European bees, except Prosopis and the parasitic species, have their hairy covering specially adapted to collect pollen. This apparatus forms a characteristic by which they are divided into two families, namely, those which collect the pollen with a brush on the lower side of the body, and those which collect it with the pencil-like hairs of the hind legs.

In the former family there are various degrees of development in the pollen-collecting apparatus, difficult alike to describe or distinguish; and as the relationship of these species to the honey-bee is but remote, we may content ourselves with glancing at this group as a whole.

The second group, on the contrary, offers a steady series of degrees of development which we may now compare with each other and with Prosopis.

Passing over the first step—sphecodes, we come to Andrena and Halictus, whose size and length of proboscis places them distinctly above Prosopis. Their visits to flowers rise from 7·4 per cent. in the case of flowers with the honey altogether apparent, to 51·6 per cent. to the flowers of complex form and with the honey entirely concealed.

The genera Eucera, Anthophora, and Sarapoda reach the highest point of intelligence as regards flowers of all our native bees, the length of their proboscis varying from ten to 21 mm., one of the humble-bees (*Bombus hortorum*) being the only one that can in this respect compare with them.

The three above-mentioned genera, out of fifty-six visits to flowers, paid none to those with the honey apparent, but 91·1 per cent. to those with either concealed honey of complex form, or with both characteristics united.

There is no further example of increased development of the proboscis in this family, but they have attained a further step in the transformation of the thigh brushes into pollen-baskets, and above all in the establishing the community of life and of labour which distinguishes the humble hive bees. From observations made on the latter, however, it appears that increased development shows a certain return to the flowers containing more visible honey, the honey bee, out of 520 visits observed, going to such flowers at the rate of 0·8 per cent., the hive-bee, 194 visits being observed, at the rate of 3·1 per cent.

The following table is fuller than the previous one :—

	a	*b*	*a* + *b*	*c*	*d*	*c* + *d*	*e*	*f*	*g*
Tenthredos	69·1	16·3	85·4	13·0	0	13·0	0	—	1·6
Hunting-wasps	44·7	19·0	63·7	30·0	4·8	34·8	1·5	—	—
Solitary bees ... ... Prosopis	22·6	22·6	45·2	33·3	7·1	40·4	11·9	2·4	0

Bombus apis	3·1	15·5	18·6	25·3	34·5	59·8	13·4	7·2	1·0

Explanation of Table—

a, flowers with honey apparent; *b*, partially apparent; *c*, honey concealed but easily reached; *d*, concealed but adapted to a short proboscis; *e*, flowers only possessing pollen; *f*, useless attempts to get honey by making a hole, as on Dielytra; *g*, flowers without honey.

The visits to the flowers with partially apparent honey $a + b$ steadily diminishes from the Tenthredos to Andrena and Halictus, but so that the diminution of the visits entirely refers to the flowers with the honey apparent, while, on the contrary, the flowers with honey partially hidden are visited with still greater frequency.

In the case of some solitary bees, the disinclination to flowers with the honey apparent has reached to their total abandonment.

The transition to social life brings the development in the second group, of which we have been treating, to an end, as, in proportion as the number of individuals in a community increases, the necessity for food forces them to seek honey where they can, and it is indeed touching to see the unwearied diligence with which the hive-bee will collect almost imperceptible drops of honey from even the smallest flowers.

The perfection which the family of bees, viewed as a whole, has attained, beginning with Prosopis, and rising to the most perfect of the solitary bees belonging to the group which collect pollen on their hind legs, consist :—

1. In the increasing development of the pollen-bearing apparatus.

2. In the prolongation of the lower part of the mouth.

3. In the increasing size of the individuals.

The first is seen best in the humble and hive-bees; the third is very marked in the humble-bee, while the length of the proboscis reaches its furthest point in Anthophora. The hive-bee has a more perfect pollen apparatus than the humble-bee, but is inferior to the latter in size and length of proboscis, and only succeeds in obtaining more honey through its more populous communities.

It is well known that as a rule every hive-bee occupied in seeking food from flowers specially devotes itself to a particular species, passing by others, however rich in pollen or honey. The advantages of this arrangement are obvious, much fewer visits being made in vain to flowers already plundered, and much greater dexterity being attained in the case of flowers with complex forms.

Two questions remain to be decided—

1. Does each individual bee collect pollen and honey from a single plant only (to which it has become adapted by instinct, *i.e.*, by inherited custom)?

2. Does the hive-bee possess a greater degree of intelligence in deciding among the different species of plants than the humble-bee and other lower forms?

The first question must be met with a decided negative; the second, as far as observation has yet gone, cannot be answered with certainty. It would scarcely be of advantage to the bee-community, whose object is the exploitation of as many flowers as possible, if its instincts as to special tribes were hereditary.

It is, on the contrary, to be observed in the hive-bee that each bee makes various essays before deciding on any special tribe of flowers. For example, we have seen a hive-bee in vain attempt to obtain the honey of *Iris pseudacorus*, and then fly to *Ranunculus acris*, which it sucked at for some time. Another more than once bored through the spur of *Orchis latifolia*, loading its head with two little clubs of pollen, and then flying to the flowers of *Lychnis floscuculi*.

A third, wandering over a field full of weeds, visited one after another *Veronica hederæfolia*, *Lithospermum arvense*, *Sisymbrium thalictrum*, and *Viola tricolor*.

These and similar facts show that there can be no question of inherited preferences for certain plants in individual bees, and that the fact of each bee being devoted to certain plants is only to be ascribed to the subordination of the interests of the individual to that of the state. The humble-bee approaches the hive-bee in the peculiarity of keeping to certain species, as well as in the number and keeping of its community. However, though chiefly confining itself to the plants accessible to it alone, as for example, *Lamium album*, &c., there are fairly numerous cases in which the humble-bee goes to other plants, and its baskets are often found full of very varied kinds of pollen.

Even in solitary bees, the special preference for special kinds of flowers is a frequent habit. For example, *Andrena hattorfiana* is found on *Scabiosa arvensis*, *Cilissa melanura* on *Lythrum salicaria*, &c.; but this preference evinced by some solitary bees for a single species of flower sufficing all their needs is radically different from the practised and exhaustive pillage of all flowers by a bee community, in which special individuals are told off to gain the produce, however small, of special families of plants. At first I believed I could answer the other question propounded above, *i.e.*, whether the hive-bee promises a higher degree of intelligence in distinguishing different genera of plants than the humming-bee and other lower forms, in the affirmative, on the ground of the following observations:—In a field grown over with weeds I saw one of our more intelligent humble-bees, *Bombus agrorum*, visit without distinction the little whitish flowers of *Viola tricolor* var. *arvensis*, and those of *Lithospermum arvense*, the same size and colour, but evidently differing in form, while avoiding all other plants. I had, indeed, seen the hive-bee mistake the flowers of *Ranunculus arvensis* for those of *R. bulbosus*, those of *Trifolium repens* for those of *Trifolium fragiferum* many times, but had then never seen it make so great a mistake as that I have recorded of the humble-bee. From this I concluded that the hive-bee is more practised in distinguishing various species than the humble-bee. As, however, I later saw the hive-bee go from the blue violet to a hyacinth of the same colour, and back again, I felt convinced that the grounds of my conclusion were somewhat defective, and I can only leave the decision of this question to further observations. As far as my own experience is concerned, I am inclined to believe that the hive-bee, as well as all other bees which we see preferring special families of plants, are much more led by colour and size than by any clear apprehension of the form of the flowers.

A. J. G. D.

AN ACCOUNT OF DUPLEX TELEGRAPHY

THE introduction of the duplex system of working not only upon land-lines, but on sub-marine cables, is without doubt the most important advance recently made in electric telegraphy.

Duplex telegraphy may be defined as the art of telegraphing in opposite directions simultaneously along one line wire.

It is claimed by M. Zantedeschi in papers read before the Academy of Sciences, Paris, in 1855, that as early as 1829 he had suggested and demonstrated the possibility of working "duplex;" but until the year 1853 there do not appear to have been any noteworthy attempts made to effect it practically. In that year, Dr. Gintl, a director of Austrian telegraphs, described a system of duplex telegraphy to the Academy of Sciences, Vienna, and practically tested it on the land-lines between Vienna and Prague.

The principle underlying this and all other systems, is that the outgoing currents at a station shall not sensibly affect the receiving instrument there, while, at the same time, the latter is free to be affected by the incoming currents, so to speak, from the other station. That is to say, no signals are made at a station by its own sending currents, unless when these are interfered with by the sending currents of the other station.

Gintl's plan was as shown in Fig. 1. The receiving instrument, R I, was wound by two separate wires, one long and thin, the other short and thick. The long wire, shown by a full line, was connected at one end to the line L, and the short wire, shown by a dotted line, was connected at one end to a local, or, as it was called, a "compensating" circuit. Both of these wires were connected at their other ends to a signalling key or sending instrument, K, having duplicate points. Two batteries, B and B′, one large and the other small, were also connected to this key in such a manner that on making contact the current from the larger battery B passed through the long coil of the instrument into the line, while at the same instant the current from the smaller battery B′, passed through the short coil and compensating circuit. These two currents were so adjusted as to balance each other in their effects on the indicator of the receiving instrument, and no signal was therefore made by the outgoing or signalling current from the battery B. Such was Gintl's arrangement at both stations, S and S′. Confining our attention to any one of these stations, say S, we see that as long as only S is sending, the receiving instrument at that station is unaffected, but when S′ is also sending at the same time, the currents in the line from S′ must interfere with the currents in the line from S, either aiding or opposing these according to the poles of the battery which are applied, and thereby disturbing the balance of currents on the receiving instrument at S, causing it to make signals. And we see also that these signals are entirely under the control of S′—that when S′ applies his battery to the line, S's instrument will make a signal, and that when S applies his battery to the line, S′'s instrument will make a signal, or that when either put "earth" to the line, that corresponding "spaces" will be recorded. The currents do not cross each other in the line, as was sometime thought, but they interfere with each other in such a way as to disturb the electric balance which independently exists at either end.

One objection, however, to this plan of Gintl's was that the lever of the key during sending interrupted the line circuit when it was between the earth and battery contacts; and another more serious objection lay in maintaining the equivalence of the two currents, as the smaller battery working through the shorter circuit lost power more rapidly than the signalling battery.

Gintl, however, in the following year (1854) obtained better success with a Bain's chemical printing instrument. Here he made the two currents oppose each other upon the chemically prepared paper and no stain was produced by the outgoing current. The sending current from the other station neutralised to a certain extent the outgoing current and the *local* current then overmastering it stained the paper and produced signals.

Early in 1854, while Gintl was still engaged in experimenting with the Bain's instrument, a great improvement was effected on his plan by Herr Carl Frischen, a telegraph engineer of Hanover. Frischen dispensed with the second battery B′ and split up the signalling current itself, causing one part to pass round one coil of the receiving instrument into the line and the other part to pass round the other coil of the instrument into the local or compensating circuit. Instead of making the two wires of the instrument dissimilar, like Gintl, he made them both alike, so that the instrument was practically wound by equal wires in opposite directions and thereby rendered *differential*. He inserted into the compensating circuit a rheostat or set of resistance coils whose resistance could be adjusted to equal the electric resistance of the line. His arrangement at either station is shown in Fig. 2. Here R I is the differentially wound receiving instrument, B is the battery, and R is the rheostat or artificial line as it was called, because of its being intended to imitate the actual line. K and E are as before, the sending key and earth plates respectively. In the act of sending a message, on making contact between the key and battery at *a* the current flowing into the apparatus divides itself at the point *b*, and part passes through the right coil of the instrument into the line, while part passes through the left coil into the local circuit. But the resistance of the local circuit being made equal to that of the line and the two coils of the instrument being electrically equal one *half* of the current will flow through one coil and the other *half* through the other coil. The coils being oppositely wound these currents will neutralise each other in their effect on the indicator or needle of the instrument and no signal will be produced as long as they flow freely. We have seen, however, that the sending at the remote station may either oppose or assist that part of the current entering the line. Thus the balance is disturbed and signals will be made on the receiving instrument of one *kind* or another according as the line current or the local current overbalance each other.

In sending by this method of Frischen's the line circuit is never completely interrupted, but it will be observed that according to the position of the key the line is either applied "to earth" direct or through the battery, or through the resistance R, and this leads to a troublesome variation in the signals.

Frischen's method was re-invented a few months subsequently by Messrs. Siemens and Halske of Berlin, who patented it in England, where, however, they were forestalled by a week by Mr. Stirling Newall, of Gateshead, whose patent bears date October 30, 1854. Newall describes substantially the method of Frischen–Siemens, and in 1855–56, successful experiments were made under his patent on the Manchester and Altringham line; but when he came to make trials upon the longer line between Birmingham and London, the *static* charge and discharge of the line was found to make false signals. Condensers or accumulators of electricity were applied to correct this disturbance with promising results, but the expense of constructing large condensers was objected to and their use was prematurely abandoned.

At this time there was a great deal of activity in the direction of duplex working displayed both at home and abroad. Besides the names mentioned, Messrs. W. H. Preece, Highton, De Sauty, and others in this country, Edlund, Bosscha, Kramer, in Germany, and Farmer, in America, were all more or less engaged in the work. In 1856 a good many lines were worked on the duplex principle in Prussia, but the time was not yet ripe for its successful introduction, and it gradually fell into disuse again. Some desultory activity was still shown here and there, however, showing that the idea had not been lost sight of. In 1862 Mr. William Hinckling Burnett patented a method of working two or even three distinct systems of telegraphy by the use of currents of different degrees of force, and in 1863 M. Maron, of Berlin, appears to have first placed the receiving instrument in the diagonal of a Wheatstone's balance. This has been called the Wheatstone bridge method in the recent revival of duplex, and it may be shown as follows, Fig. 3.

Here r and r' are two of the branch resistances of a Wheatstone's balance; the line and artificial line, or rheostat, R, forming the other two branches. The receiving instrument, R I, is inserted in the "bridge" wire. In sending, the current from the battery B splits at b, and part passes by r into the actual line, while part passes by r' into the artificial line. If r be equal to r', and the actual line be equal to the artificial line, the current will divide itself equally, and the potentials, or, as it may be called, the electric levels, at c and d, will be equal, and there will be no tendency for a current to flow through the cross channel or "bridge wire," and the receiving instrument will not, therefore, be affected. When, however, the line currents are interfered with by the sending currents of the distant station, this balance will be disturbed, currents will flow through the "bridge wire," $c\,d$, and the receiving instrument will signalise. The resistance, w, may with some slight advantage be made equal to the battery resistance. It will be seen that in the balance method, as in the differential method, the principle consists in dividing the signalling current between two circuits whose electrical properties are practically the same, and so placing the indicator between these as to cause them to neutralise each other's effect upon it.

The credit of reviving the lagging interest in duplex telegraphy appears to be due to Mr. Joseph Barker Stearns, of the Western Union Telegraph Company, United States, who, in 1868, experimented on the New York to Boston line, and subsequently achieved considerable practical success on the overland lines of the company with which he was connected. In 1872 Stearns came to England and patented his system, which practically embraced the differential and Wheatstone balance methods, as described, with the addition of a novel sending key and a condenser attached to the rheostat or artificial line.

With the differential method his arrangement is as shown in Fig. 4, where K is the new sending key, and C is the condenser. The advantage of Stearns's key is that the manipulating lever, *a* (which is permanently connected to the battery B), makes contact with the lever *b* (which is permanently connected to the receiving instrument), before *b* is disconnected from the earth wire *w*, so that, in sending, the line may always be "to earth," either through the battery B, or the earth wire *w*. Thus the evils of both Gintl's and Frischen-Siemens's methods are obviated, inasmuch as the line circuit is not only never interrupted, but the resistance of the earth connection may be kept the same by keeping *w* equal to the resistance of the battery. In order to prevent the wasting of the battery while it is short-circuited for a moment through the key, the resistance, *w′*, may be added to the battery resistance, and *w* then made equal to both.

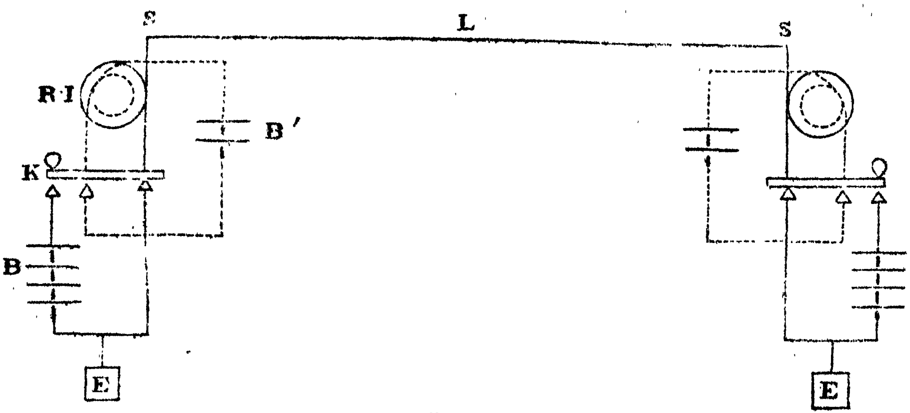

FIG. 1.

The condenser was applied, as in the experiments made under Newall's patent, to correct the effects of the static induction of the line upon the instrument. Condensers or accumulators had been in common telegraphic use for producing induction since Bagg's patent in 1858 and Varley's in 1860, and it is obvious that the sudden inductive charge and discharge of the line could be counterfeited by attaching a condenser or other inductive apparatus to the artificial line. This inductive effect is in general only sensible on land-lines upwards of 300 miles long. The induction between the wire and earth is then sufficient to maintain a sensible static charge on the wire, independently of the signalling *currents*, so that on working the sending key, and thus charging the line, the sudden static charge is for a moment added to the signalling current or dynamic charge; and, on the other hand, when the key is made to earth the line, this static charge flows back again out of the line to earth. Thus two sudden jerks or "kicks," as they are called, are produced on the electric balance, and false signals are thereby made. When, however, a condenser or other inductive apparatus is added to the artificial line, so as to give it induction, too, the charge and discharge "kicks" of the artificial line may be made to counterbalance those of the actual line. In short, it is clear that if the electrical properties of the artificial and of the actual line in induction, resistance, and insulation are approximately equal, a duplex balance can be effected between them.

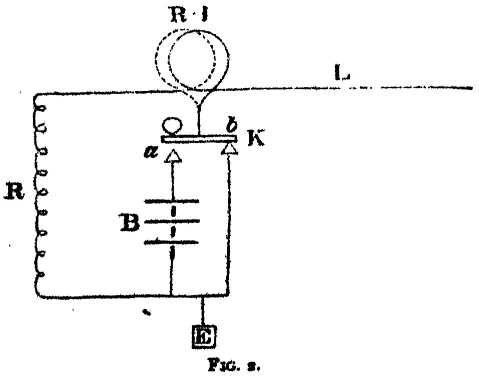

FIG. 2.

Stearns's key and earth connections were subsequently in the same year (1872) re-invented by Herr J. F. Naes, of Rotterdam.

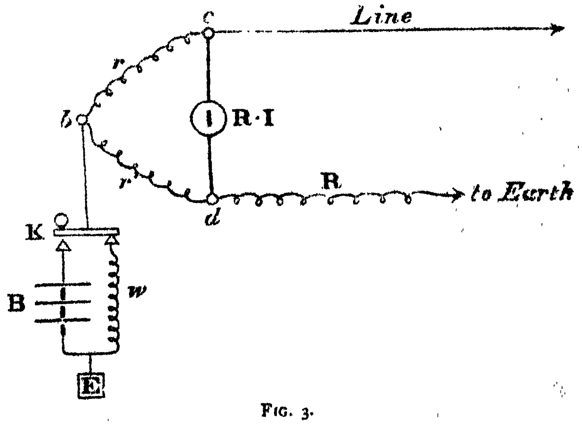

FIG. 3.

In 1873 Mr. George Kift Winter, Telegraph Engineer of the Madras Railway of Arconum, British India, patented in England a method of duplex by opposed batteries, a principle which it appears had been previously applied by Mr. Moses G. Farmer, of New York, in 1858. Winter's method consisted in keeping the batteries at both ends of the line continually applied to it, so that their like poles opposed each other and a standing balance was maintained on the receiving instrument at either station, which could be disturbed by the operator at the other station. This arrangement is shown in Fig. 5.

Here, as will be seen, the batteries are equal and are constantly connected to the line, so that their like poles oppose each other through the differential coils of the receiving instrument and the line. Thus the balance is maintained. But when at station S, for instance, contact is made with earth by the keys K, the battery B will be cut off from the line, and the current from station S′, no longer opposed, will make a signal on the instrument there. Winter's method was tried with some success in India. Up to this time experiments had been for the most part confined to land-lines.

Attention now began to be turned to submarine cables, and Winter proposed the use of secondary batteries, made of plates of one metal (as lead) immersed in a single fluid (as sulphuric acid), in order to provide the large electric induction necessary to the artificial line, or by application in some particular way to the receiving instrument, so as to counterfeit the induction "kicks."

Stearns, also, in the same year, took out further patents principally for the purpose of extending his system to cable work. For example, he patented combinations of condensers and resistance coils to represent an artificial cable. This, however, had been done as early as 1862 by Varley, for the purpose of making an imitation cable for use as a "test" circuit. Varley distributed his condensers along his resistance circuit in the manner shown in Fig. 6, so as to approximate to the uniform distribution of resistance and capacity in a submarine cable; but Stearns confined himself to attaching his condensers all at one point of his rheostat, and modifying their charges in various ways by means of resistance coils. Stearns also proposed various additional arrangements for superimposing "kicks" on the receiving instrument which should counterbalance the inductive "kicks" known to be very violent and difficult to obviate on submarine cables. He also describes a method of constructing his condensers in the form of a submarine cable; and, apparently for the purpose of economising material, he further proposes to employ Gintl's original plan of two batteries; but in this case the stronger battery would be used to charge the artificial line, so that, with less capacity than the actual line, its inductive "kick" might be made equivalent to that of the latter. In fact, Stearns and Winter appear, naturally enough, to have striven rather to effect the duplex balance by some *device* or by an artificial line approximately *similar*, instead of aiming at one approximately *equal* to the actual cable.

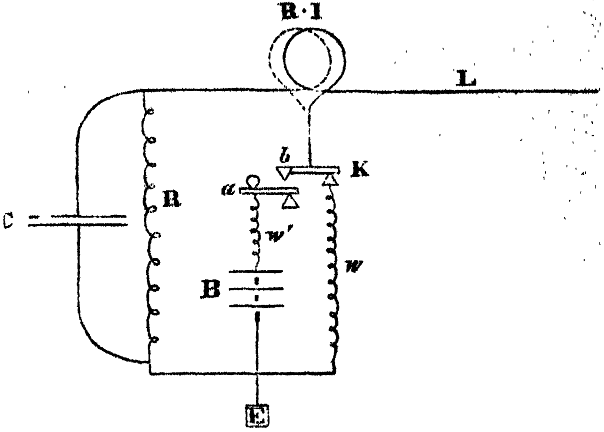

Fig 4.

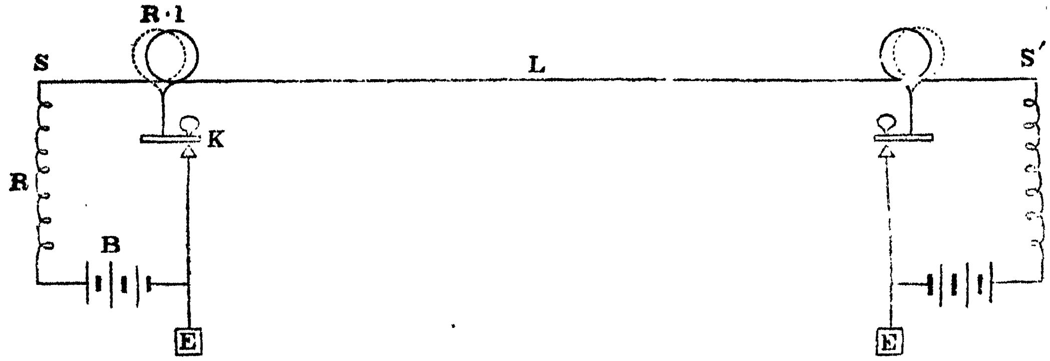

Fig. 5.

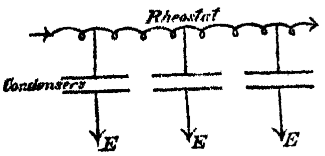

Fig. 6.

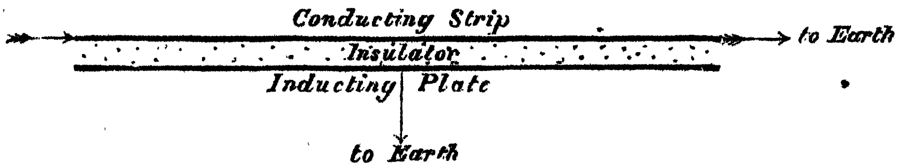

Fig. 7.

In 1874 Mr. Louis Schwendler, of Calcutta, patented a system founded on the Wheatstone balance principle, and applicable to submarine cables by the use of resistance coils and condensers, or of a cable itself as an artificial line; but Schwendler's system is only novel for the ratios between the resistances of the balance which it lays down. The best results are said to be given when the resistances r', R and w, Fig. 3, are each one-half of the resistance of the line, and r is made equal to one-sixth of the resistance of the line.

The first successful trials in submarine duplex that we hear of are mentioned in the *Journal of the Society of Telegraph Engineers* for 1874. From this it appears that Messrs. De Sauty and Harwood, both of the Eastern

Telegraph Company (which had been encouraging experiments), had succeeded in effecting a balance, in 1873, on the Gibraltar-Lisbon cable by the use of the Wheatstone balance method and Varley's artificial line. Also, in a letter to the *Telegraphic Journal* for 1874, by Mr. B. Smith, of the Eastern Telegraph Company, we learn that he had succeeded in effecting a balance on one of the Company's cables between Malta and Alexandria in July, 1873, so that he could receive messages while sending a distance of 911 nautical miles. In September of the same year Mr. Smith also reported good success on the Malta-Gibraltar cable, a distance of 1,121 nautical miles. We are not aware, however, that these methods have been in practical working for any length of time.

In 1874 Mr. John Muirhead, of the firm of Messrs. Warden, Muirhead, and Clark, telegraph engineers, Westminster, took out a patent for a new form of condenser, or inductive-resistance, so made as to imitate a submarine cable, and ostensibly for the purpose of duplex telegraphy. The inductive resistance is formed by taking two strips of tinfoil and laying one over the other separated by an insulator. One strip forms the conducting circuit of the artificial line, the other forms the outer, or inductive coating, and is connected to earth. The current is passed through the conducting strip and exposed throughout its entire length to the induction of the other strip or sheet in the same way that the current in the conductor of the cable is subjected to the induction of the earth throughout its length. The principle of Muirhead's artificial line is shown in Fig. 7, where the arrows represent the local current passing along the conducting strip while being at the same time retarded by the induction of the other strip, or inducting plate, which is connected to earth.

This artificial, or model cable, can be made to have the same resistance, capacity, and even leakage, per knot, that the actual cable has, so that it can be made practically equal in its electrical properties to the actual cable. It may be employed either with the differential or Wheatstone balance methods. In either case the local current passes through the conducting strip to earth, experiencing the same resistance and retardation that the signalling current experiences in the cable. It therefore balances the signalling current in its effects on the instrument. Its advantage over Varley's "artificial line" consists in the closer equivalence to an actual cable that it admits of. Subsequent patents of Mr. Muirhead describe various adjustments to be used in connection with the artificial line for the purpose of refining upon the balance.

In July, 1875, this system, which is hitherto the most successful of all in submarine duplex, was first tried on the Marseilles-Bona (Algeria) cable, a length of 448 nautical miles. In the spring of this year it was established for permanent working on the Marseilles-Malta cables of the Eastern Company, a length of 826 nautical miles, and also on the Suez-Aden cable, a length of 1,461 nautical miles, but in an electrical sense, one of the longest of existing cables. These are the first practical successes in submarine duplex telegraphy, and they also prove the feasibility of working cables of any length by this advantageous method.

MUSEUM SPECIMENS FOR TEACHING PURPOSES[1]

II.

ARTICULATED or mounted skeletons are divided into two classes: 1. Natural; 2. Artificial. The two processes may, however, be more or less combined in certain cases.

Natural skeletons are not macerated. The bones are merely cleaned by the hand, assisted by scalpel, scissors, and brush; the subject being placed in water during the intervals of the operation, to get it free from blood, and to soften the parts removed. Everything having been taken away, except the bones and the ligaments which unite them, the skeleton is fixed in the required attitude by external supports, and allowed to dry. This process is commonly adopted with very small mammals, birds, reptiles, and especially fish. It has the advantage of involving less labour and skill in articulation, and of affording a trustworthy record of the number and relations of the bones, especially the vertebræ, about which, in an artificially articulated skeleton, unless prepared by very competent hands, there always may be doubt. On the other hand, such skeletons are far less useful for the study of the details of their structure, they not only cannot be taken to pieces, but the extremities of the bones are actually concealed by the dried ligaments. The latter, moreover, often become brittle with time; and in the case of the smaller specimens, will break unless handled with great care. In such cases it is often advisable to strengthen them with isinglass, or when more support is required, some strands of cotton-wool steeped in melted isinglass or glue make excellent artificial ligaments.

2. Artificial skeletons are those in which the bones have all been separated and completely cleaned by maceration, or one of the processes substituted for it, and then joined together again by wire. The reconstruction of such skeletons is technically called "articulating." To perform it properly some knowledge is required of osteology, so that the bones may be placed correctly, which of course is of the utmost importance, and also some mechanical skill in drilling the holes in the bones, and in adapting and fitting the wires and metal supports, and several instruments are required, not needed in the preparation of natural skeletons, such as drills, pliers, wire-cutters, files, &c.

The best wire is iron-tinned, which does not rust, and is now sold at most ironmongers. For very fine work, iron wire plated with silver, and for still more delicate operations, especially in fishes' skeletons, thin silver wire may be used. Copper wire is too soft and flexible for almost all articulating work, and is apt to give a green stain to bones which contain any grease, and so should be avoided. Brass tubing of various sizes is now extensively used in articulating, and for larger animals, iron supports, which will have to be made by the blacksmith specially for each subject.

However great the knowledge of the articulator, it is always best to take precautions before macerating an animal, that there should be no mistakes in arranging the bones properly, especially in the case of rare and little-known specimens. The skin and the greater part of the soft parts having been removed, and the bones roughly prepared as for a natural skeleton, should then be divided into several parts. The sternum with the costal cartilages should be removed by cutting through the latter at the junction with the ribs, and cleaned in water without macerating, and then allowed to dry in their natural form on a block of wood, cut to the requisite shape and size. If this part goes into the macerating vessel, the cartilages will be lost, and the thorax can then only be restored in an imperfect manner. The limbs should be separated, and if each is macerated in a separate vessel, much trouble will be saved in sorting the small bones of the feet. If there is any doubt about articulating them correctly, it is best to take them out before they have actually separated, and clean them off and articulate them at once, at all events drilling the holes for the wires while they are still in natural apposition. The vertebræ may be allowed to come apart and macerate together, as there is never any difficulty in placing them in their natural sequence. The hyoid bones should be sought for in the throat, and cleaned and preserved separately, and small sesamoid bones about the feet and behind the knee-joint in most animals, so commonly lost in museum specimens, should be looked for and preserved, as well as the rudimentary clavicles of the carnivora and the pelvic bones of the whales and porpoises. When the relations of any bone to another, especially of the sesamoids above spoken of, or the chevron bones under the caudal vertebræ, are likely to be lost in maceration, they should always be observed, and either notes or drawings made of them, or they should be marked with fine holes, made with an Archimedian drill (an essential instrument to the articulator). By making two holes on different bones opposite to one another before the bones are separated, or several holes arranged in patterns, most important records can be preserved, and such small holes do not damage the bones, as they can be filled up afterwards with putty, or frame-makers' composition.

---

[1] Lecture at the Loan Collection of Scientific Apparatus, South Kensington, July 26, 1876, by Prof. W. H. Flower, F.R.S., Conservator of the Museum of the Royal College of Surgeons of England. Continued from p. 146.

The perfection of a skeleton, an object always to be aimed at, ll greatly depend upon the attention paid to all the small ecautions just named, and others which will suggest themlves in the course of the process.

In skeletons, as ordinarily articulated, the principal object ems to be to preserve the general appearance of the framework the animal and to make the whole firm and strong, at the me time showing as little as possible of the supports necesry to hold it together. Every bone, even to the skull and wer jaw, is immovably fixed, and strong wires, or irons, acrding to its size, are made to traverse the interior of the limb nes, fixed into the stand below, and connected with the main pport, which runs along the centre of the bodies of the rtebræ from head to tail.

Such skeletons are little better for the detailed study of teology than are natural skeletons, and they are inferior, inasuch as there is no guarantee against errors on the part of the ticulator, unless he be of known knowledge and experience.

The improvements in articulating skeletons that I am about to ing before your notice were commenced about twelve years o, and are mainly due to the ingenuity and skill of the veteran ticulator to the Museum of the Royal College of Surgeons, my mesake, Mr. James Flower, who has successfully put into actice various ideas and suggestions which have occurred to e during the time of my conservatorship.

The object aimed at is to mount a skeleton which will give a rfect idea of the form and proportions of the animal and show e bones in their relative position, and at the same time allow ery part of each bone to be separately examined. Any portion hich is required for examination must be made capable of being moved without disturbing the rest of the skeleton. The skull, e lower jaw, the different vertebræ, the pelvis, the limb bones ust be all separable.

Such a skeleton of course cannot be supported on its own nbs, like one of the old kind, as the bones of all the extremies may be removed one by one if necessary, leaving the trunk *situ.* It will also be somewhat less firm and stable, and must treated with care, as in fact a delicate and somewhat complited instrument would be.

The details by which this principle is carried out vary greatly, d must be adapted to every different animal, and may probably yet still further modified and improved. The illustration sent the Exhibition is a very fair example. It is a skeleton of a aly anteater or pangolin (No. 3,812). The two principal echanical arrangements adopted are simple enough.

They are, first, the use of brass tubes, into which wires of corsponding size are made to slide. This is the best method of conecting two parts, which have to be separated at pleasure. When ecessary the tubes and wires may be flattened to prevent them rning. The principal supports are made of tubes fixed into e wooden stand below, and into the upper end of which a short ire fixed in the bone to be supported slides. These tubes can adily be riveted to each other so as to make a branched support hen required.

The second mechanical contrivance consists in the use of visted or plaited wires as a means of movable connection tween bones which need not be completely separated, but only ent upon each other as by a hinge. For instance, the principal nes of the limbs are connected by a strand of wires, twisted gether like a rope, passing on one side of the joint. Each end inserted in a hole drilled in the bone, and fixed by means of nall wedges of wood or metal. These joints are so stiff as to main in any position in which they are placed, and yet are rfectly flexible and durable. The vertebræ are connected, by ing fixed by wires, on to a plaited band, passed along the ferior surface of their bodies, where nothing of importance is ncealed by it. Since this skeleton was mounted it has, however, been found better in many cases to run the plaited wire rough the canal, so that it is perfectly out of sight. Though atness in the mountings of a skeleton is certainly a desideratum, is better to have any number of external supports to the bones, an either to fix immovably or to mutilate them, as was often one in the old plan, in order to allow of the introduction of the ncealed supports.

The ribs, sternum, and sternal ribs are usually mounted in e solid piece, separable from the vertebral column, so that the ticular ends of all the ribs can be easily examined. In some ses it is found better to string the vertebræ upon a stiff rod, several pieces of rods, connected by sliding joints, from which ey can be removed in succession. In fact, as before said, the odifications of these processes are numerous, but they can best be appreciated by examining a few mounted specimens, and may be further developed by the suggestions of experience.

In addition to the complete mounted skeleton, museums will be expected to have separated portions of the bony structures exhibited in a manner that the student can study them. The skull especially must be treated in this way. For many years skulls of various animals have been prepared at Paris "*à la Beauchêne*," and there are some good examples in the Exhibition contributed by Tramond, including an entire human skeleton (No. 3,913, also 3,915 and 3,918, skulls of man and turtle).[1]

All the bones are separated and fixed by brass bands and wires, at short intervals from each other, so as to allow of their complete form being examined.

The sliding joints formed of brass tubing will be found a great improvement in such specimens, as it allows the complete removal of any portion required for more particular examination. An example will be seen in the skull of a sheep (No. 3,819), contributed by Mr. E. T. Newton, of the Museum of Practical Geology.

A single bone is best mounted by driving a sharpened wire into its lower surface, which wire slides into a tube of corresponding diameter fixed in the wooden stand; in this way all the series of separate bones in the Museum of the College of Surgeons are mounted. The stands are made of turned wood, circular, polished, and black. All the brass work in them and the mounted skeletons is coated with a layer of black japan varnish.

I must not omit to mention a method of mounting skeletons devised and recommended by Prof. Huxley, the details of which have been developed by Mr. Newton from processes initiated at the College of Surgeons. There is an example in the Exhibition in the skeleton of a dog, No. 3904*a*. Each of the bones of the skeleton is mounted separately with wire and tubing, as in the single bone just spoken of, but they are arranged on a single flat board in definite order, the vertebræ in succession along the middle, and the limbs on each side, each bone being near its actual position of the body. Skeletons so prepared can be arranged one above the other in a cabinet, each board running on ledges in the sides of the cabinet like drawers. They are very convenient for study and demonstration, especially for advanced students; but they are not so suitable for public museums or for elementary teaching, as they convey no idea of the general appearance, form, and proportions of the animal from which they are prepared.

Certain portions of the skeleton, especially of the lower vertebrates, are never ossified, but remain permanently in a cartilaginous condition, and when dried, shrivel and contract into small shapeless masses. But it would be often desirable, in a dry skeleton, to keep them if possible, if only to preserve the positions and relations of the surrounding bones. For instance, the axial portions of the skeleton of many fishes' heads are entirely cartilaginous, and so are the carpal bones of the crocodile. Such parts ought to be modelled either in soft wood or in the composition of whiting, resin, and linseed oil used by the picture-framemakers, which is soft and plastic when recently made, but sets to an almost stony hardness. Specimens of the application of such modelling may be seen in the Museum of the College of Surgeons.

Besides the skin, and the skeleton, many other parts of the body are frequently preserved in a dry state in museums. When bottles and spirits were very dear this method was much more attended to than at present, and it was extensively used for injected preparations, showing the course of the blood-vessels, and even dissections of muscles and nerves, as well as for the hollow viscera, such as the stomach, cæcum, &c., which were inflated, dried, and then varnished. There are many objections to such preparations. All soft and fleshy parts, when dried, contract so much as to give little idea of their appearance in the recent state, and in doing so disturb the relations of the parts in contact with them. Inflated organs, which look very well for a time, are apt to collapse, and they are all liable to decay and to perish from the attacks of insects. To guard against this it is absolutely necessary that the preparations should be thoroughly soaked in alcoholic solution of corrosive sublimate, or some other such poison, before the drying process commences. In Italy, especially in the Museum of Comparative Anatomy at Pisa, I have seen beautiful and very instructive specimens of viscera preserved in a dried state, and it is to be regretted that none have found their way into this Exhibition, as they might have stimulated us to endeavour to do something to improve the art, which in most of our anatomical museums is now almost obsolete.

---

[1] I should also call attention to a beautiful human skeleton by the same exhibitor, for the purpose of practising dislocation (No 3,914), in which the principal bones are connected by coiled spring wire. This method has long been used on a partial scale, as for attaching the lower jaw to the skull, but is not so convenient as the one described above, as the elasticity of the spring is always an impediment to the free examination of the bones.

The methods of preserving the hard parts of invertebrate animals, such as insects, molluscs, and coral animals, in a dry state, are so generally understood, and so fully described in many special treatises,[1] that there is no occasion to detain you with them at present. The best illustration in the present collection of this branch of the subject is the very valuable and instructive preparation of the Exoskeleton of the common lobster (No. 3904 *a*) prepared by Mr. E. T. Newton, and exhibited by Prof. Huxley, which is a model of a class of preparations which might be largely employed in teaching zoology. I may also call attention to a small series of preparations contributed by Prof. H. Landois, of Münster (No. 3878), which purport to show something of the life history and habits of several species of insects, an idea which might be more fully carried out in biological museums, and to the typical collections of the shells of molluscs exhibited by Mr. R. Damon (Nos. 3808 to 3811).

(*To be continued.*)

OUR ASTRONOMICAL COLUMN

The New Star in Cygnus.—On the evening of December 13 this star, as regards brightness, was about midway between 75 Cygni and Bessel's star, Weisse XXI. 1004, the *Durchmusterung* magnitudes of which are 5·2 and 6·5 respectively, giving for the new star a magnitude of about 5·8 to 6·0, as stated last week. On December 20 it was not more than 0·25m. brighter than Bessel's star, indeed at moments it was difficult to say which was the brighter of the two; its present rate of decline is therefore slower than during the first ten days after the discovery. In the foggy sky of December 20, there was a yellowish tinge in its light, not perceptible in Bessel's star. A further careful search through our star-catalogues has failed to reveal any previous observation of a star in this position. It falls in one of the two zones, the re-observation of which has been undertaken at Bonn.

The Binary Star 6 *p* Eridani.—It may be hoped that some one of our southern observers is putting upon record measures of this double star, of which, so far as we know, none have been published since those of Mr. Eyre B. Powell at Madras, at the beginning of 1861, when the angle of position was 253°, and the distance 4″·9. Altering the node in Capt. Jacob's second orbit to 109° 40′, and assuming the peri-astron passage to have occurred 1817·64, with a period of revolution of 117·48 years, the measures from 1835 to 1861 are very closely represented, without change in inclination, distance of peri-astron from node, or semi-axis major. Dunlop's measures in December, 1825, which are of doubtful interpretation, would, with Jacob's correction, differ 6½° from the computed angle. Later measures than those of 1861 are required for a decision on the true form of orbit. α Centauri and *h* 5114 (R.A. 19h. 17m. 50s., N.P.D. 144° 34′ for 1876) are equally to be recommended to the close attention of the southern astronomer.

When a systematic remeasurement of the double stars of Sir John Herschel's Cape catalogue, which are out of reach in these latitudes, is undertaken (and we know of no more desirable or more interesting work in the miscellaneous astronomy of the other hemisphere), a large accession to the list of binaries may be anticipated. Perhaps M. O. Struve has not—in 24 Comæ Berenicis—detected the most rapid of the revolving double stars, which it may remain for a southern observer to bring to light.

Periodical Comets in 1877.—Of the known comets of short period, only one—that of D'Arrest—has been predicted for the ensuing year, though if the elements of De Vico's comet of 1844 have not undergone a violent change since that appearance, it may be expected to be in perihelion also within the next twelvemonths.

D'Arrest's comet will arrive at its least distance from the sun on May 10, but will not be nearest to the earth until October; its positions when observations should be most feasible, are not favourable for observers in the northern hemisphere. M. Leveau's elaborate ephemeris affords every possible assistance towards its detection. At its last visit in 1870 this comet was excessively faint, and was not observed at more than four or five of the numerous European Observatories.

Surely there must soon be an end of the dearth of discoveries of new comets which has prevailed since the beginning of December, 1874.

Ancient Solar Eclipses.—In Nature (vol. xv., p. 116), Sir George Airy notes a difference in the path of the shadow in the total eclipse of B.C. 763, June 14, given in this column (p. 65) from that defined by a direct calculation from Hansen's Tables. In explanation of this difference it should be stated that our elements of the eclipse of B.C. 763, as also (with one exception) for other eclipses to which we have from time to time referred, are obtained by the use of Damoiseau's Lunar Tables of 1824, with the main arguments, and one or two of the principal equations adapted to the elements resulting from Sir George Airy's laborious discussion of the observations of the moon at the Royal Observatory, Greenwich, from 1750 to 1830, combined with M. Leverrier's Solar Tables, and the introduction of Hansen's last values of the terms in longitude, anomaly and node depending on the square of centuries.

METEOROLOGICAL NOTES

The Storm of March 12, 1876.—We turned with considerable interest to the account of this storm, which passed over the south of England on March 12, as published in the *Journal* of the English Meteorological Society for July. The interest was all the greater, seeing that the account was drawn up, at the request of the Council of that Society, by Mr. Scott, assisted by Messrs. Gaster and Whipple, that descriptions of the same storm had been previously published by Prof. Quetelet, Dr. Neumayer, and the late M. C. Sainte-Claire Deville, and that another paper on the same subject was intimated by Dr. Buys Ballot. The widespread interest which this storm has called forth is seen at once on looking at the nine weather maps and tables of Mr. Scott's paper, which show it to be one of the most remarkable storms of recent years, whether regard be paid to the rapid rate of its propagation eastwards, estimated by Dr. Neumayer at seventy-seven miles per hour over part of its course; to the rate of the barometric fluctuation, almost unprecedented in these islands, the barometer at Kew having risen 0·407 inch during the two hour from 2 to 4 P.M.; or to the violent contrasts of temperature and weather on the two sides of the storm at comparatively short distances apart. To illustrate the subject with greater fulness a woodcut is given showing the automatic registrations of the different meteorological instruments at Kew, and tables of pressure and temperature for every ten minutes during the most interesting phase of the storm. To these curves a noteworthy and novel feature is added in the form of a curve showing the electrical changes from positive to negative, and *vice versâ*, at the time. The *hourly readings of their self-recording instruments* for March were moreover published shortly after by the Meteorological Office. On turning to these two barometric records taken from the same instrument at Kew, referring to the same time, and published by the same authorities, and comparing them together, we meet with nothing but confusion. Of the whole of the eleven instances on which readings are printed in the two records for the same instants of time, no two agree, the eleven differences being in order, + 0·006, – 0·024, – 0·008,

---

[1] The most recent being "Notes on Collecting and Preserving Natural History Objects," edited by J. E. Taylor, Ph.D., and published by Hardwicke and Bogue, London, 1876.

−0·040, −0·020, −0·001, −0·040, −0·004, −0·012, −0·027, and +0·003 inch. Whether or not the readings in the paper be reduced to sea-level, no information being given on this point, the whole observations ot at least one of these two records are entirely wrong. In explanation of discrepancies previously pointed out, it was stated by the office that the original photographs may not admit of a precision closer than 0·020 inch. In this case, however, such an explanation is out of the question. Equally loose and inaccurate are the descriptions of the Kew curves, even though the main design of this costly system of registration is to furnish data for exact comparisons being instituted among the different meteorological elements. Thus it is stated that the electricity, having been strongly negative, returned again to positive between 6 and 8 A.M., whereas the change occurred all but instantaneously about 6.45 A.M.; that simultaneously with the time of maximum temperature, about 12.20 P.M., the wind, which had been west "suddenly became north," whereas the change was not of such a character as to be described by the words simultaneous and sudden, seeing that about fifteen minutes elapsed as the wind veered from west to north; that "the barometer rose rapidly until 4 P.M., at an average rate of about 0·005 per minute," whereas this rapid rate of increase of pressure was spread over no more than the fifty minutes from 2 to 2.50 P.M. It is needless to remark that the data of this singular storm thus put before us are worse than useless and it may be also stated that a number of the barometric observations at Kew, as published in the *Hourly Readings* for March, are of such a character as to render a verification by comparison with the originals very desirable.

DIURNAL BAROMETRIC RANGE AT LOW AND HIGH LEVELS.—We have recently received from Mr. W. W. Rundell, a paper on this important subject, published about two years ago in the *Journal* of the Meteorological Society of London, based on observations made under the direction of Gen. Myer during May, 1872, on Mount Washington, New Hampshire, at heights of 2,639 and 6,285 above the sea, hourly from 6 A.M. to 6 P.M., and at 9 and 12 P.M., and at Portland, Maine, 54 feet above the sea and near the coast, at 7 and 8 A.M., and at 2, 5, 9, and 12 P.M. The means of atmospheric pressure, temperature, and humidity, are given for the different hours of observation, to which are added interpolated values for the hours of the day for which no observations were made, by drawing a fair curve passing through the observed values plotted off on a moderately large scale. These various averages are laid down in sets of curves accompanying the paper. The point of interest raised by such a discussion consists in the presentation of these three vital meteorological elements at three stations not far apart from each other, but very differently situated as regards height above the sea, and the probability that some light may thereby be thrown on one of the most difficult problems in physics. On examining the curves the attention is at once arrested by the remarkable character of the curve of the diurnal barometric range at Portland, which represents the morning maximum as occurring at 6 A.M., and the afternoon minimum at 2 P.M. Deductions of a somewhat large nature are drawn from the times of occurrence of these and others of the maxima and minima of the paper tending to show that they stand to each other in certain definite relations. Since, however, the facts of observation afford no instance of the morning maximum occurring in May at such places as Portland at 6 A.M., and the afternoon minimum at 2 P.M., we were led to calculate afresh the averages from Gen. Myer's figures with the result that the averages of the six hours of observations published in the paper are all in error in amounts varying from + 0·027 inch to − 0·004 inch. The fresh averages, it may be remarked, give an amplitude of range and hours of occurrence of the extremes accordant with what has been observed in latitudes and situations similar to that of Portland in May. It is obviously premature to discuss the various points raised until the necessary data be put in order before us, and the interpolated values for the unobserved hours be laid down on a method based on a wide knowledge of observed values for the same hours at places similarly circumstanced.

THE CLIMATE OF GENEVA.—A large work on this subject has just been published by Prof. Plantamour, in which are discussed with clearness, precision, and great fulness, the observations made at the observatory during the past fifty years, on temperature, pressure, moisture, rainfall, winds, clouds, and thunderstorms. The hourly averages of the different elements of each month for each year and for groups of years are given, as well as the averages for each day of the year, and the average or sums of the pentades and months for the long periods during which the observations have been made. There is thus amassed in a handy form in one volume of 263 pp. 4to., data for the elucidation of the climate of this part of Switzerland, as well as for larger inquiries which fall to be dealt with by comparative meteorology, and for the investigation of many cosmical questions. Among the specialties of the climate of Geneva, the most interesting, perhaps, are those which arise from its position with reference to its lake. The variations in the direction and force of the wind during the day show land and lake breezes of a strongly marked character—the breeze from the lake prevailing at those hours of the day when the temperature of the land is in excess of that of the lake, and the land-breeze during the rest of the day. In December, when the land at no hour of the day is warmer than the lake, no breeze from the lake prevails. In January, however, the breeze from the lake begins slightly to prevail, and in an increasing degree in succeeding months, forming a marked feature in the climate of the town during the greater part of the year, and leaving its impress in nearly all directions on the different meteorological elements. During the winter months, when no breeze from the lake prevails, or but a feeble one, the vapour curves show only one daily minimum, occurring about sunrise, and one maximum about 2 P.M.; whereas during the other months, from March to October, there occur two daily minima, one about or shortly before sunrise, and the other from 2 to 4 P.M., and two maxima, one from 8 to 11 A.M., and the other from 6 to 10 P.M., according to season. Equally marked are the curves of the hourly variations of cloud, the maximum during the winter months occurring about sunrise and the minimum about sunset. During the warm months, however, there are two daily maxima and minima—the first maximum occurring about or shortly after sunrise, and the second, which is by far the larger of the two, about 6 P.M., and the two minima shortly after midnight and from 9 to 11 A.M. These variations in the moisture of the air of Geneva are attributed by Plantamour to the condensation and evaporation which take place at the surface of the earth, and to the ascending and descending aërial currents consequent on the diurnal march of the temperature. These are undoubtedly true causes concerned in bringing about diurnal hygrometric changes, but they are insufficient to explain the strongly-marked double maxima and minima observed at Geneva. This will be evident by a simple reference to the hygrometric curves for such places as Valentia, Toronto, and Oxford, which either exhibit no second maximum at all, or if they do, so faintly marked as to form no outstanding feature of the curves. The explanation, in all probability, of this peculiarity of the Geneva hygrometric curves is to be found in the relative size of Lake Geneva which is just large enough to occasion a strong breeze during the day from the lake *all round its shores.* On the setting in of the breeze, the air having been some time previously resting on the surface of the lake is therefore moist, and while this continues the first daily maximum is reached. As, however, the breeze continues, *the air feeding it must necessarily, owing to the com-*

parative smallness of the, lake come from higher strata of the atmosphere, and since this air has been but a brief time in contact with the surface of the water the lake breeze becomes constantly drier till the afternoon minimum from 2 to 4 P.M. The breeze thereafter diminishes in force, the air consequently becomes moister till the greater maximum is attained about the time of the day when the breeze from the lake falls to a calm. This special feature of the climate of Geneva well deserves the closest investigation, particularly in its relations to the curves of temperature, pressure, and clouds. Among the other points discussed may be mentioned an examination of Deville's cold and warm periods of the year by the long series of the Geneva Observations; a comparison of the temperature of the water of the Rhone, as it issues from the lake, with that of the air, showing the mean annual temperature of the water to be 3°·7 higher than that of the air, a point of some importance in connection with questions affecting oceanic circulation; the distribution through the year of strong northerly and southerly winds, and the variations, regular and irregular, in the amount and duration of the rainfall.

CLIMATE OF LUND.—A paper of considerable value has been published by H. A. V. Tidblom, in *Lunds Universitets Arsskrift*, tom. xii., on the meteorological observations made at the observatory at Lund from 1741 to 1870. The observations, which are very fully discussed, embrace the temperature, winds, rain, snow, thunderstorms, and auroras, and their great value lies in the long period, viz. 130 years, over which they extend. The highest observed temperature during the 118 years ending 1870 was 94°·1, and the lowest — 13°·9, both occurring in 1845. Northerly and easterly winds prevail in winter and spring, northwesterly in summer, and south-westerly in autumn—these winds being of special interest from their relation to the prevailing winds in the south of Norway in the corresponding seasons. Hail falls on an average 5 days in the year, snow 37 days, and rain 122 days. March is the month of smallest and least frequent, and August of greatest and most frequent rainfall. Thunderstorms reach the maximum in the last half of July and first half of August, very few occurring from the middle of October to the middle of April. The greatest number of auroras occur in April and September, and the variations through the different years are very great, a remarkable maximum period occurring from 1776 to 1790, since which latter date the number has been singularly few.

WEATHER SUMMARY.—M. H. Tarry's *Histoire de l'Atmosphère* for July and August, 1876, has been received. The publication, which recently began to be published in *Les Mondes*, aims at giving a summary and discussion of the meteorological elements of the northern hemisphere, which it is possible to collect within a month or two of their occurrence. It is thus calculated to be a useful supplement to the weather maps of Europe and America, and to the International Meteorological Observations of the United States, and as such it deserves the active support of the meteorologists of different countries.

INFLUENCE OF FORESTS ON OZONE.—In a note by M. L. Fautrat in the *Bulletin Hebdomadaire*, No. 475, of the Scientific Association of France, it is shown from observations made at Halatte and Ermenonville, that less ozone was observed in forests, particularly forests of pine, than in the open country, and more ozone at a height of 46 feet above the ground than near the surface.

NOTES

THE Loan Collection of Scientific Apparatus is to be finally closed on the 30th inst.

THE Danish Geographical Society enters upon its existence under royal auspices. In accordance with the invitation of the King of Denmark, the first public session was held in the royal palace at Copenhagen, on December 22, accompanied by appropriate festivities. The King has accepted the position of Protector of the Society, while the Crown Prince is active president.

THE veteran chemist, Prof. F. Wöhler, has been elected president of the German Chemical Society for the coming year.

A TELEGRAM received by M. Sidoroff from Capt. Wiggins, and communicated by the former to the St. Petersburg papers, announces that on December 13 Capt. Wiggins and his shipmaster, M. Svanenberg, left Krasnoiarsk on their way to St. Petersburg.

OUR readers may remember that at the International Conference on the means for exploring Central Africa thoroughly and systematically, held at Brussels last September under the presidency of the King of Belgium, invitations were issued to the different countries represented to form local committees for the furtherance of this object. The German National Committee was formed last week under the presidency of Prince Henry VII. of Reuss, and embraces many of the most distinguished names in the empire. A committee has already been intrusted with the duty of preparing the statutes for a permanent association, the German Society for African Exploration, which is to be under the patronage of the Crown Prince, and expects to enter vigorously and energetically upon its chosen field.

THE *Daily News* correspondent at Rome writes that the Marquis Antinori has sent to the Italian Geographical Society a long account of the journey of the Italian African Expedition of which he is leader. The expedition has, after many hardships and delays, reached Shoa, the king of which has received the members in his capital, Licce, with the greatest hospitality. The Marquis has taken steps to make Shoa a scientific *entrepôt*, as a basis of operations for exploring the equatorial lakes. When the letter left the Marquis was preparing an extended scientific report of his journey to be forwarded to the Italian Society by a courier.

IN the last session of the Berlin division of the German and Austrian *Alpen-Verein*, Dr. Scholle delivered an elaborate address on the orography of the Bernese Alps. He regards them as distinguished from the mountains of other alpine regions by the following peculiarities:—The valleys are unusually deeply cut. The mountains inclosing these valleys are remarkable for their relative as well as their absolute heights, and the horizontal projection of their tops lies always at but a short distance from the bottom of the valleys. Finally, the topmost points of the mountains are generally visible from the valleys, and their commanding appearance imparts to the landscape its most picturesque and magnificent features.

THE *Bulletin* of the French Geographical Society for November contains a paper by Dr. Jules Carret on the Displacement of the Polar Axis, in which he gives a summary of arguments in favour of displacement which will appear at length in a work about to be published by him.

THE following particulars are given by Prof. Desor in the last number of the *Bulletin* of the Society of Natural Sciences at Neuchâtel, as to the burial-ground of the inhabitants of the lake-dwellings discovered last winter on the shores of the Lake of Neuchâtel at Auvernier. The burial-place is about 100 feet distant from the well-known lake-dwellings of this locality, at the foot of a hill, and it was shut up by some 7 feet of earth washed by rains from the slopes of the hill. It has a quadrilateral form (1·6 metre long and 1·12 broad), and is built of flat granitic stones covered with two large flag-stones of gneiss, these last necessarily having been cut artificially. The burial-place thus belongs to that class of dolmens which are known in England as "stone-cists," and it establishes therefore a new link between the true dolmens and the lake-dwellings. Assiduously watching the excavation, Prof. Desor ascertained that he had really to do with a grave (that of a family, or of a clan), not merely with a receptacle of bones, the relative positions of bones proving that complete corpses were deposited in the grave, probably in a sitting position. The number of individuals buried must have been from fifteen to twenty. It was very difficult to obtain well-preserved skulls, the bones being much deteriorated and the excavations not having been made with the desirable accuracy; but some better preserved skulls show a close likeness to those found in other lake-dwellings, and especially to the skull of this kind described by MM. Rutimeyer and His in their "Craniologie Helvétique;" they belong to the mesaticephalous (semi-long) form known as the "Sion group," which form is also the true Helvetic. This form, which has been found in the stone age, continues to appear throughout the bronze and stone ages, constantly increasing in size, and showing a more and more developed, higher and broader, forehead; and it differs from the present Helvetic form not in kind but only by the degree of its development. The implements found in the grave are stone and bone implements belonging to the age of polished stone. But along with them were also found bronze implements (a perforated disc, a ring, and a pin), which thus establish the long missing link between the lake-dwellings of the stone age and those of the bronze age, both of which have representatives at Auvernier. The importance of the Auvernier grave is thus very great, as it gives new proofs in support of the alleged unity and continuity of races of prehistoric man during the stone age and that of the bronze. Some bronze implements implying a somewhat higher degree of culture, together with a bead of yellow amber and a skull, were found in the neighbourhood of the grave, on a somewhat higher level; they belong probably to a more recent period. It is proposed by the Neuchâtel Society to undertake further excavations in the same locality.

THE earthquakes which were felt in the Canton of Neuchâtel last spring (from April 2 to May 16) are the subject of two interesting communications by Prof. Desor and Dr. Tribolet, published in the last number of the *Bulletin* of the Neuchâtel Society of Natural Sciences (vol. x. part iii.). Dr. Tribolet, in addition to particulars of the earthquakes of this year, gives also a list of those known to have been felt in the canton since 1313. From this list we see that earthquakes were especially numerous during the seventeenth century, comparatively rare during the eighteenth, and totally wanting during the first half of this century, until 1852, when they begin anew to be frequent, twenty-four shocks having been felt from that year to the end of 1875. The earthquakes of last spring began with a strong one on April 2, at 5.55 A.M.; a second shock followed on April 30, and then, until May 16, no less than eleven shocks were felt in the canton at short intervals. The region of the shocks was generally limited, only two of them having been felt beyond the frontiers of the canton. As to their causes, Professors Desor and Studer, and Dr. Tribolet come unanimously to the conclusion that they have nothing to do with volcanic causes; but that the rocks of the Jura, forming a varied series of harder and softer strata, the latter mostly undermined by subterraneous streams and numerous caverns, it is very probable that the earthquakes are due to the crumbling of undermined strata, the seat of these crumblings being probably at a depth of about 1,400 feet, where friable dolomites and saliciferous marls are covered with hard muschelkalk. The exceptionally abundant rains of last spring must have contributed to the saturation of rocks with water.

PROF. LIVERSIDGE, of the University of Sydney, has published a report on the disease known as "rust" which has been causing great havoc among the sugar-canes in Queensland. This disease appears to have been first observed in the colony in 1870. Though most of the varieties of cane seem to have been more or less affected, the Bourbon was the one upon which the disease was first noticed, and this kind has since suffered more than any other; soil and climate have also assisted its progress in a marked degree; thus it is said to have been almost exclusively confined to dry, porous, sandy soil, and to have been more virulent after unusually wet and cold seasons. The juice obtained from diseased canes shows a lower density than that obtained from healthy ones, and the sugar is more difficult to make. With regard to his microscopical examination of the diseased canes, Prof. Liversidge says he failed to detect anything which could possibly be considered as the cause of the disease; though the canes were affected by minute fungoid growths, they were not sufficient to account for the actual disease, and were undoubtedly the consequence and not the cause. Red spots are found on all the plants, healthy as well as unhealthy, but more abundantly on the latter. It is to the presence of these red spots that the name of *rust* has been applied generally to the disease in Queensland. The fungoid growths are said to bear a very strong resemblance to a large group of very common microscopic fungi—the *æcidiacei*, to which order they are said probably to belong. Notwithstanding the prevalence of these fungoid bodies, and after a minute examination and analysis of various soils, the author of the report arrives at the conclusion that the disease has not been due to any one cause but rather to a combination of numerous complex, and more or less obscure causes, which are attributed to the system of cultivation adopted by the planters, the land being exhausted without a proper return being made to it.

IMPORTANT results have been obtained by parties of the United States Geographical Survey west of the hundredth meridian, under Lieut. George M. Wheeler, corps of engineers, in geology and natural history, Mr. H. W. Henshaw, the zoologist of the California Section, having made large collections of the vertebrate fauna, including every family of birds occurring in the West. The streams explored in Nevada and California were found to abound in fishes of the genus *Catostomus*, and among the specimens collected it is not improbable some species may be found that are new to science. In the reptilian collection are several snakes belonging to the genus *Eutania*, and a new species of lizard. In entomology the *Orthoptera* and *Coleoptera* are largely represented, including some rare species from the Alpine mountain region. Careful investigations were made in geology by Mr. A. R. Conkling, and the collections made taxed the facilities for transportation, the rocks gathered being chiefly igneous and metamorphic, including syenite, granite, basalt, &c. The predominating rock in the region thus far examined by the California scientific expedition is grey syenitic granite, containing numerous crystals of black hornblende. Several mines were explored and described in detail. In palæontology there were few collections, fossiliferous formations being rare. From the sandstone quarries in Ormsby County several specimens of the genus *Unio* were obtained, these tertiary fossils being the only representatives of extinct fauna observed.

WE have received a paper, "On the Larger Divisions of the Carboniferous System in Northumberland," by Mr. G. A. Lebour, being a reprint from the *Proceedings* of the North of England Institute of Mining and Mechanical Engineers, vol. xxv. Discussing the stratigraphical characters of the different members of the Carboniferous series, the author advocates a new subdivision of it into two stages, an Upper and a Lower, instead of the three adopted now; the blending together under a common name of "Bernician" of the Yoredale Rocks, the Scar Limestone series, and the Calcareous and Carbonaceous groups which are incapable of natural division, and the additions of the Tuedian and of the so-called Upper Old Red to the Lower Carboniferous beds. A plate showing the stratigraphical changes undergone by the Carboniferous series from Derbyshire to Berwickshire, on which the views of Mr. Lebour are based, accompanies the paper.

THE General Council of Hautes-Alpes has decided to organise a special meteorological service for the purpose of carrying out the system of weather-warnings for agriculture for that department analogous to what have been established in other departments of France. The height and other physical peculiarities of the department make this a valuable addition to this system of warnings which is being gradually established over France with marked success.

A MEMOIR on the Ophite of Pando, in the province of Santander, by Don Francisco Quiroga y Rodriguez, which has just been published in the *Anales de la Soc. Esp. de Hist. Natural.*, is of considerable interest to petrographers, as it discusses the microscopic structure and mineralogical constitution of a rock of decidedly peculiar character, and at the same time enables us to realise the points of resemblance and difference between it and the similar rocks of the Pyrenees, described by Prof. Zirkel, and those of the province of Cadiz, concerning which Mr. Macpherson has recently given us such very interesting details. The rock in question is suspected to be of Triassic age, and among other features of interest presented by it we may mention the existence in it of a mineral which appears to possess characters intermediate between those of augite and diallage.

THE following further Saturday evening lectures have been arranged for in connection with the South Kensington Loan Collection of Scientific Apparatus. We do not yet know whether the closing of the Collection will interfere with their delivery:—December 30.—Prof. W. F. Barrett, on "Some of the Practical Applications of Electricity as Illustrated by Instruments in the Loan Collection." January 6.—Alexander J. Ellis, F.R.S., on "The Nature of Chords in Music, illustrated by Appunn's Apparatus." January 13.—Dr. B. W. Richardson, F.R.S., on "Stephen Gray and the Discovery of Electric Conduction." January 20.—Prof. Garrod, on "The Instruments exhibited by M. Marey, specially with reference to the Flight of Birds and Insects." January 27.—W. Chandler Roberts, F.R.S., on "The Means adopted for securing the Accuracy of the Coinage." February 3.—Prof. Osborne Reynolds, on "Vortex Motion." It is intimated that the Collection will be closed after Saturday, the 30th inst.

WE are glad to see that an effort is being made to give the people of Hertford some knowledge of science, of the value of which they seem somewhat ignorant. Mr. Percy Smith and Mr. Vincent Elsden have commenced a course of experimental lectures on Chemistry and Physics, which, to judge from the syllabus, is likely to prove both interesting and instructive to those who are wise enough to attend.

THE curious phenomenon of a ball being supported in air by a strong air current directed obliquely 35° to 40° from the vertical, has lately been exhibited in Philadelphia. Various explanations of it have been attempted by engineers and others. M. Reuleaux (in *Poggendorff's Annalen*), rejecting previous explanations, offers the following:—The pretty thin air current, on reaching the ball, is deflected on all sides, and therefore more or less rarefied in its interior. Accordingly the atmosphere presses the ball in the direction of the greatest rarefaction, or the mean force of the rarefactions, towards the orifice. The weight of the ball acts vertically downwards. Equilibrium occurs between the obliquely-acting force of the current and the two forces just named, when the mean force of the latter is parallel to the action of the current. This can only take place when the ball has its centre under the axis of the current. There is then a pair of forces which put the ball in rotation. If the finger or a rod be brought to the place of supposed minimum pressure on the ball, the latter is forthwith driven off (as the [illegible]) or falls down.

FROM a recent report on the cultivation of the vine in Madei we are told that the *Phylloxera vastatrix* has partially attacke and destroyed many plants in some districts, but the evil has n discouraged the renewal and extension of plantations. The improved method of treating Madeira wines have rendered the more agreeable to the prevailing taste of consumers, and th demand for them is steadily increasing in every market. I Teneriffe many landowners have likewise turned their attentio again to the cultivation of vines, and the wines of the island a thus increasing annually in quantity. The *Oidium* is graduall dying out, and where it still appears is successfully checked b sulphuring. The *Phylloxera* has as yet not appeared in any c the vineyards.

FROM the Annual Report on the Brisbane Botanic Garder we gather some valuable and interesting facts relating to th acclimatisation of economic plants. Of the three most extensively cultivated tropical plants—sugar, coffee, and tea, we lear that at present forty varieties of sugar-cane are grown in th garden, and that there is such a large and continuous demand fc plants of such varieties as are known to be not yet subject t disease, that the director has recommended the setting apa from the Botanic Garden of a piece of ground to be used as nursery for sugar and other plants of commercial value. It i satisfactory to know that with regard to coffee the plants of th ordinary kind (*Coffea arabica*) in the experimental plantatatio are all healthy, and show not the slightest sign of disease eithe from the *Hemileia vastatrix*, or any other cause. The norther districts, especially the sheltered ridges of the Hubert an Endeavour rivers are said to be the most suitable to the profitable cultivation of coffee, and some thirty acres of land on th Lower Hubert is to be put under this cultivation during th ensuing season. Of the Liberian kind (*Coffea liberica*) some seed have been sent from England, and these are growing into perfectly healthy plants, some of which, indeed, have been alread distributed. Though the tea plantation is reported to be in flourishing condition and numbers of plants have been distributed, the cultivation of tea, it is said, does not attract th attention it deserves owing to the high price of skilled labou required in the preparation of tea as a commercial article. Amon other plants of interest introduced to the Garden may be mentioned the Paraguay tea (*Ilex paraguayensis*), which seems to b thoroughly well adapted to the climate of Queensland. Mr Hill reports that the demand for it has of late very largely increased. The Balsam of Tolu (*Myroxylon toluifera*), the nev tanning plant (*Balsamocarpon brevifolium*), the Sumatra rubber plant (*Urceola elastica*), and the Siam Gamboge (*Garcinia morella* var. *pedicellata*), all seem to be doing well. The consideration o the introduction of foreign grasses and other plants as well fo fodder purposes as for renovating old pastures, has occupied som attention in Queensland, and the result is that many of our well known meadow-grasses as well as the *Trifoliums Medicagos*, an *Melilots* have established a similar reputation in the new to tha which obtains in the old. The only unsatisfactory part of Mr. Hill' report is that in which he tells us of the destruction and probabl extermination of indigenous plants. Thus, in certain district within the Colony, some trees formerly plentiful have almost dis appeared, or are but rarely found. The Queensland Nut (*Macadamia ternifolia*) is an instance, in districts abounding with i some years ago, it is now difficult to find even a single specimen This has been caused in consequence of numbers of them havin been cut down chiefly by South Sea Islanders for the purpose o more easily obtaining the fruit at the expense of the destructio of the tree. A similar fate seems to await the *Cycas media*. It found between Port Denison and Cooktown, and the flour obtained from its seeds forms one of the principal articles of food, in certain seasons, of the aborigines of that part of the Colony During the visit of the North-East Coast Expedition of 187 quantities of it were found in the deserted camps, and unless preventive measures are promptly taken, from the wholesale destruction now going on, it will speedily share the fate of the *Macaamia*.

At the two meetings of the St. Petersburg Chemical Society, September 28 and October 19, many papers of interest were read. We notice among them a valuable report of M. Bogussky on his researches into the velocity of chemical reactions and on its dependence upon the degree of concentration of the solutions; a paper of M. Alekséeff on the mutual solubility of soluble liquids, the conclusions of which were, however, warmly criticised; a paper of Prof. Butléroff on the di-isobutylene, classing this body among the homologues of the etylene series; and of M. Kovalefsky on the amount of mechanical power disengaged during chemical reactions, those of the sulphates of copper and zinc having been begun with in the course of researches undertaken by the author.

Mr. Thomas Southwell, of the Norfolk and Norwich Naturalists' Society, writes with reference to our notice of Mr. Marsham's "Indications of Spring" (Nature, vol. xv. p. 128), that this remarkable series of observations commenced in the year 1736, is still continued by the Marsham family. In 1789 Robert Marsham communicated his observations to the Royal Society, they were read on April 2 and printed *in extenso*, in the *Philosophical Transactions* of that year. Robert Marsham died in 1797, and the observations were continued by his son Robert to the year 1810. From that time till 1836, no record was kept, but in the latter year a third Robert Marsham resumed them, by whom, and his son, the present Rev. H. P. Marsham, they have been continued to the present time.

The experienced Arctic cruiser, Mr. Lamont, writes to the *Times* of Tuesday in reference to Dr. Petermann's recent letter to the Geographical Society, expressing his decided conviction, founded on his own extensive experience and that of many other practical Arctic men, that all round the North as round the South Pole, there lies an eternal mass of ice a thousand miles in diameter, and perhaps miles thick in the centre. He does not believe that either "ship, sledge, man, beast, bird, or balloon, will ever get across it."

The additions to the Zoological Society's Gardens during the past week include two Bonnet Monkeys (*Macacus radiatus*) from India, presented by Mr. Peter Varwell and Mrs. Leopold Evans; a Chinese Eyebrowed Thrush (*Leucodioptron canorum*) from China, presented by Mrs. Arabin; a Short-eared Owl (*Otus brachyotus*), European, presented by Mr. Josh. Lee; three Golden Orioles (*Oriolus galbula*), a Redwing (*Turdus iliacus*) European, presented by Mrs. A. H. Jamrach; a Dunlin (*Tringa cinclus*), European, presented by Mr. F. Cresswell; a Snowy Owl (*Nictea nivea*) from Lancaster Sound; a King Parrakeet (*Aprosmictus scapulatus*) from New South Wales; a Greater Sulphur-Crested Cockatoo (*Cacatua galerita*), from Australia, deposited.

SCIENTIFIC SERIALS

Poggendorff's Annalen der Physik und Chemie, No. 11, 1876.—On the nature of elastic reaction, by M. Braun.—On the gliding of gas on glass walls, by M. Warburg.—Report on experiments of Dr. Root of Boston, on penetration of platinum by electrolytic gases, by M. Helmholtz.—Researches on the heat phenomena in the galvanic battery, and on electromotive forces, by M. Edlund.—Electro-magnetic properties of unclosed electric currents, by M. Schiller.—On the reply of M. Schlösser and the asserted preferability of ebonite for the discs of influence-machines, by M. Holtz.—Observation on the division, among two acids, of the positive metal in a galvanic battery, by M. Fuchs.—On phenomena of motion in electrified surfaces of mercury, by M. Herwig.—On the galvanic behaviour of gold, and a new kind of Nobili rings, by M. Schiel.

The *Naturforscher* (November, 1876).—From this number we note the following papers of interest:—On the transparency of the water of Lake Leman, by F. A. Forel.—On the meteoric iron of Nentmannsdorf, near Pirna (Saxony), by F. E. Geinitz.—On the absorption of albumen by the leaves of *Dionæa muscipula*, by A. Fraustadt.—On the simultaneous occurrence of sugar and oxalate of lime in plants, by G. Kraus.—On electrical dust figures in space, by E. Lommel.—On some experiments with plants in coloured light, by G. Kraus.—On the dependence of the co-efficient of interior friction of gases from temperature, by A. von Obermayer.—On ascending air-currents, by Herr Crompton.—On microscopical inclosures in South African diamonds, by E. Cohen.—On the deterioration of air through artificial light, by Friedrich Erismann.—On the mechanics of breathing and the circulation of matter in the animal body, by E. Pflüger.—On the chemical composition of beech-leaves and fir-needles in different states of development, by L. Dulk.

Morphologisches Jahrbuch, vol. ii. part 3.—On the skin and dermal sense-organs of Urodela, by F. Leydig, with four plates.—On the metamorphosis of Echiurus, by W. Salensky, one plate, giving four stages of development.—On the exoskeleton of fishes, part 1; a long and valuable paper, by O. Hertwig, with six plates, dealing with the exoskeleton of Siluroids and Accipenseroids.—Prof. Gegenbaur has another contribution on the morphology of the limbs of vertebrates.—R. Wiedersheim discusses "the most ancient forms of the carpus and tarsus found in existing amphibia."

Zeitschrift für wissenschaftliche Zoologie, vol. xxvii. Part 3.—On the development of the lower jaw in Mammalia, by Dr. J. Brock; a histological memoir.—An account of the anatomy of *Rhynchelmis limosella*, with four plates, by Franz Vejdovski.—On the organisation and minute structure of the Daphnidæ and other Cladocera, by Dr. C. Claus, with four plates.—Description of a new hydroid polyp related to Allman's family Pennaridæ, by F. E. Schulze.

The *Journal de Physique* for November, 1876, contains papers on illumination of transparent and opaque bodies, by M. Lallemand; application of very thin layers of gold to cathetometers and other instruments of measurement, by M. Govi.—On the distribution of magnetism in cylindrical bars, by M. Bouty.—On the physical properties of gallium, by M. Lecoq de Boisbaudran.

SOCIETIES AND ACADEMIES

London

Mathematical Society, December 14.—Lord Rayleigh, F.R.S., president, in the chair.—Mr. R. F. Davis, B.A., and Mr. H. Weston Eve, M.A., head-master of University College School, were elected members.—Prof. H. J. S. Smith, F.R.S., read a paper on the conditions of perpendicularity in a parallelopipedal system (the subject was of interest to crystallographers as well as to mathematicians).—Mr. Glaisher, F.R.S., gave an account of a paper by Prof. Cayley, F.R.S., on the condition for the existence of a surface cutting at right angles a given set of lines. "In a congruency or doubly infinite system of right lines, the direction-cosines α, β, γ of the line through any point x, y, z, are expressible as functions of x, y, z, and it was shown by Sir W. R. Hamilton in a very elegant manner that in order to the existence of a surface (or what is the same thing, a set of parallel surfaces) cutting the lines at right angles, $\alpha\,dx + \beta\,dy + \gamma\,dz$ must be an exact differential; when this is so, writing

$V = \int(\alpha\,dx + \beta\,dy + \gamma\,dz)$ {we have $V = \varsigma$, the equation of the system of parallel surfaces, each cutting the given lines at right angles." The author obtains his results from the analytical equations of a congruency, viz., $x = mz + p$, $y = nz + q$, where m, n, p, q are functions of two parameters, and m, n, are given functions of p, q. The condition he gets for the existence of the set of surfaces is—

$$(1 + n^2)\frac{dm}{dy} - (1 + m^2)\frac{dn}{dx} + mn\left(\frac{dm}{dx} - \frac{dn}{dy}\right) = 0.$$

He verifies his results in the case of the ellipsoid.—Prof. Clifford, F.R.S., communicated two notes on the orthogonal transformation, and additions to former papers on transformation of elliptic functions.—Mr. Tucker read portions of papers by Mr. F. W. Frankland (New Zealand), on the simplest continuous manifoldness of two dimensions and of finite extent, (communicated by Mr. Spottiswoode, F.R.S.).—On the theory of electric images and its application to the case of two charged spherical conductors placed opposite one another, Mr. W. D. Niven.—On viscous fluids, and Quaternion forms of some general propositions in fluid motion, Mr. J. G. Butcher (communicated by Mr. G. H. Darwin). An easy method of finding the invariant equation expressing any poristic relation between two conics, Prof. Wolstenholme.

Geological Society, December 6.—Prof. P. Martin Duncan, F.R.S., president, in the chair.—Thomas Collinson, P. Lindsay Galloway, the Rev. George Middleton, S. H. Needham, Maskell Wm. Peace, Nathaniel Francis Robarts, and John Stirling, were elected Fellows of the Society.—The President announced the sad loss the Society had sustained in the death of Mr. David Forbes, F.R.S., one of its secretaries, which took place on the morning of Tuesday, December 5. On this account the only paper read was on the intrusive character of the Whin Sill of Northumberland, by Mr. W. Topley, F.G.S., Assoc. Inst. C.E., Geological Survey of England and Wales, and Mr. G. A. Lebour, F.G.S., Lecturer on Geological Surveying at the University of Durham College of Science, Newcastle-on-Tyne. The Carboniferous Limestone series of the north of England contains a bed (or beds) of basalt, known as the "Whin Sill," regarding the nature of which opinion has long been divided. Some writers regard it as truly interbedded and contemporaneous; others look upon it as intrusive, and as having been forced laterally between the planes of bedding. The latter opinion is that held by the authors. Amongst the practical miners of the north of England there are very few who will admit any doubt that the Whin lies evenly, and at one constant horizon, amongst the strata. Clear cases to the contrary are looked upon as merely local variations, possibly due to successive eruptions of submarine lava. The work of the Geological Survey has shown that the Whin Sill lies at different horizons in different places: sometimes it even lies above the Great Limestone itself. In other words, *the Whin Sill, which is supposed to mark the base of the Yoredale series, sometimes lies above the limestone which forms the top of that series.* With the disappearauce of the supposed base-line of the Yoredales goes also any good reason for drawing a line here at all. The authors traced the Whin Sill through Northumberland, as far north as Dunstanborough Castle, showing the varying positions at which it occurs in the Limestone series, and noting points of interest in some of the sections. The Whin shifts its position amongst the strata to the extent of 1,000 feet or more. It frequently comes up in bosses through the bedded rocks, and bakes the beds above it quite as much as those below, especially when those beds consist of shale. As to the age of the Whin Sill, nothing definite can be said.

EDINBURGH

Royal Society, December 18.—Sir William Thomson, president, in the chair.—The following communications were read:—On the roots of the equation $\rho \phi \rho = 0$, by Gustav Plarr, communicated by Prof. Tait.—Applications of the theorem that two closed plane curves cut one another an even number of times, by Prof. Tait.—On the distribution of volcanic *débris* over the floor of the ocean—its character, source, and some of the products of its disintegration and decomposition, by Mr. John Murray, communicated by Sir C. Wyville Thomson.—On new and little-known fossil fishes from the Edinburgh district, No. 1., by Dr. R. H. Traquair.—Note on the Ruff (*Machetes pugnax*), by Prof. Dans.

MANCHESTER

Literary and Philosophical Society, November 6.—Charles Bailey in the chair.—Wealden fossils from Columbia, South America, by John Plant, F.G.S.—The raised beaches of County Antrim, their molluscan fauna, and flint implements, by Mark Stirrup, F.G.S.

November 14.—E. W. Binney, F.R.S., F.G.S., president, in the chair.—Notice of a passage in Clement of Alexandria on the origin of certain arts and customs, and their introduction into Greece, by William E. A. Axon, M.R.S.L., &c.

BOSTON

Natural History Society.—Mr. S. H. Scudder's contributions on the orthoptera continue to be among the most important papers published by this society. His "century" of new forms has reached its sixth decade. His latest published paper is [illegible] Descriptions of new Generic Forms, and an Alphabetical Synonymic list of the described Species." This extends over fifty pages, and will be of great use to entomologists.—W. H. Niles has contributed a paper on the geological agency of lateral pressure, exhibited by certain movements of rocks, referring especially to observations in sandstone quarries at Berea, Ohio, and in limestone quarries at Lemont, Illinois.

VIENNA

Imperial Academy of Sciences, October 19, November 16, 23.—The following are some of the papers read:—Researches on the contractility of the capillaries, by M. Stricker.—On the integration of linear differential equations of the second order through simple quadratures, by M. Winkler.—On the discriminants of the Jacobi covariants of three ternary quadratic forms, by M. Igel.—On the fresh-water fishes of South-Eastern Brazil, by M. Steindachner.—On the absorption spectrum of hypermanganate of potash, and its use in analytical chemistry, by M. Brücke.—On the magnetic observations of the Austro-Hungarian Polar Expedition, 1872-74, by M. Weyprecht.—On the action of bromine on succinimide, and a new way of forming fumaric acid, by M. Kisielinski.—On the velocity of propagation of sound-waves from explosion, by M. Mach.—Three papers by M. Velten (sealed packet). 1. On the transference of material particles by the electric current; 2. On the polar and magnetic behaviour of plant-cells; 3. On the magnetic behaviour of portions of the cell contents.—On the heat-conductivity of ebonite, by the Secretary.

GENEVA

Physical and Natural History Society, November 2.—M. Lucien de la Rive gave an account of his researches on the specular reflection of surfaces covered with hairs, these being considered as cylinders with circular base. The condition necessary for a cylinder to present an edge of specular reflection is that the axis of the cylinder be found in the plane normal to the bissectrice of the angle of the luminous and visual rays. It results that it is only possible to have a luminous angle by starting from a certain inclination of the visual ray. This principle is proved mathematically. It is applied to bodies of various forms, and explains the apparently abnormal play of light on children's heads, for example, and on any surface covered with hair. (Vide *Archives des Sciences Physiques et Naturelles*, t. lvii, p. 219, Nov. 1876).

THURSDAY, JANUARY 4, 1877

THE FARADAY LECTURE FOR 1875

The Life Work of Liebig in Experimental and Philosophic Chemistry. By A. W. Hofmann, F.R.S., &c. Delivered before the Chemical Society of London. (London: Macmillan and Co.)

IN this volume we have given us a sketch of the labours of Liebig in the domain of Pure and Applied Chemistry, and also an account of his manifold investigations in the direction of its Application to Agriculture and Physiology.

Prof. Hofmann has been induced to take the works of this great chemist as the theme for the Faraday lecture, not only from its being a subject in itself rich in most interesting matter, but, that from Liebig's studies on the relation and mutual bearing of the facts discussed by him, he was led to the conception of general laws elucidating chemical phenomena; thus standing beside Faraday as a fit representative of our century to future generations. Notwithstanding the great reputation Liebig now possesses, Prof. Hofmann seems to think that at the present time, we being almost contemporaneous with this great chemist, are not in a position to give to his works such appreciation as will be yielded them in the future; on this point Prof. Hofmann says:—

> "As those who wander in a mountain chain cannot appreciate the sky-reaching grandeur of its lofty peaks as well as those who remotely from the plains beneath contemplate its snow-crowned summits, so we, the contemporaries of Faraday and Liebig cannot perceive the full dignity of their commanding forms—the philosophic pinnacles of this century—as they will hereafter appear to distant generations of posterity. In these days Faraday and Liebig will be looked up to with such reverence as it is ours to offer to the mighty spirits of the past—to such giant figures as those of Galileo, Kepler, Newton, and Lavoisier. And as that bright constellation shines on us from the misty darkness of the past, so will the names of Faraday and Liebig—stars of co-equal lustre—throw forward their bright beams on our successors through the far-reaching vista of ages yet to come."

Although expressing himself at the outset embarrassed by the richness of the subject, and consequently the difficulty of making any proper classification or selection of the many interesting investigations and discoveries to be discussed, Prof. Hofmann must be congratulated on the very successful result which has crowned his endeavours.

Commencing with a short review of the general work of Liebig with regard to the elaboration of apparatus and analytical methods for chemical research, Prof. Hofmann proceeds to speak of the great power Liebig had in imparting knowledge to others, and his influence over the mind of his pupils. He next draws attention to the resemblance between the labours of Liebig and Faraday in abstract science, and the abundant results they have produced in their applications to the useful arts.

In the field of agricultural chemistry, in his investigation of the laws regulating the growth of plants, we learn from Prof. Hofmann that Liebig first penetrated the doubt and uncertainty which had previously existed, establishing with certainty the relation which exists between the growing plant and soil and air in which it lives. Standing as a monument of his most exhaustive researches on this point, we have his two works: "Chemistry in its Application to Agriculture and Physiology," and "The Natural Laws of Husbandry," this latter work constituting the first perfect treatise on the philosophy of agriculture which had appeared up to that time. To Liebig is also due the knowledge we now possess, that for proper vegetable growth the plant must be supplied through the land with those constituents which are found in its ash; and, as a sequence following from this, the fact, that should the soil become deprived of such constituents, it will be unfit for further plant growth till the proper saline ingredients are returned to it. With the knowledge acquired on such points he was naturally led to the production of artificial manures as a means for the fertilisation of land impoverished and exhausted by the crops grown upon it.

Passing from Liebig's labours in agricultural chemistry to those in the higher branch of biology, we find his discoveries producing no less perfect and important results. Although many isolated researches, as those of Chevreul, Berzelius, Gmelin, and Tiedeman, had been already conducted on certain constituents of the animal economy, still we owe to Liebig the collection of these widespread attempts into a "focus" for the elucidation of the phenomena of animal life. Of Liebig's chemico-biological work perhaps the best instances we can refer to are his "Investigations into the Origin of Animal Heat," his "Theory with regard to the Nutrition of Animals," and his "Doctrine of the Origin and Function of Fat in the Animal Economy." In the first of these inquiries he reviews the ideas of Lavoisier and Laplace, and the experiments of Dulong and Despretz, pointing out the errors of experiment the two latter investigators had fallen into, and from his own minute calculations proving the sensible heat of the animal body to be explained by the processes of combustion carried on within the organism. From his inquiries into the chemical nature of food, Liebig was led to his theory that the vegetable stands in a position intermediate between the mineral and the animal. The animal being unable to assimilate inorganic compounds, the vegetable acts as a means for transforming the mineral molecules into those of a higher order fit for the proper maintenance of the animal organism. The facts necessary for the support of his theory are to be found in the identity in composition of the nitrogenous principles, animal and vegetable, albumin, casein, and fibrin; a fact previously pointed out by Mulder, but exactly determined through analysis either by Liebig or his pupils.

In the views promulgated by Liebig that it is in the animal organism, through the transformation of starch, sugar, &c., that the chief formation of fat takes place, he was led into a long and animated controversy with Dumas and Boussingault; but in this, as in other of his discussions, experiment has decided in favour of Liebig. Although the experiments of his opponents proved the existence of fat in vegetables, it was nevertheless in quantities quite insufficient to account for the amount found in animals when fed artificially on vegetable food alone. Like his investigations in agricultural chemistry, Liebig's discoveries in the biological branch yielded their proportion of practical applications, and from his investigations of the composition and nutrition of the animal body arose the methods now used for the preparation of condensed food and for its preservation without decomposition.

On examining the purely scientific work of Liebig brought before our notice by Prof. Hofmann, the reader is at once struck by the varied nature of the researches. In his experiments on the cyanogen group, resulting from his examination of the fulminates, we are led back to some of the earliest stages of Liebig's scientific career. In this investigation, published at the age of nineteen and detailing experiments extending over two years, we have accurate proof given us of the very early age at which he had recognised the natural tendency of his mind. His experiments proving the fulminates to be isomeric with the cyanates brought him in contact with Wöhler, already working on the same ground, this friendship being soon destined to exercise a most important influence upon organic chemistry.

Liebig's investigations upon alcohol and its derivatives are interesting, not only from the fact that it was from his earlier experiments on this body proceeded the discovery of chloral and chloroform, but also that in his endeavours to elucidate the constitution of alcohol he was led into a long protracted discussion with Dumas and Boullay, a discussion resulting in the victory of Liebig. It would be impossible here to give a detailed notice of the remaining investigations of Liebig touched on by Prof. Hofmann in his discourse; it will be sufficient for us to mention Liebig's researches on the group of benzoic compounds, his discoveries in uric acid and its derivatives, executed in conjunction with Wöhler, and his elaborate work on the constitution of the organic acids.

Many as Liebig's experimental researches were he still found time for literary labour. It would be almost sufficient to mention the work founded by him, in conjunction with his friends, Wöhler and Hermann Kopp, as early as 1832, a work then and now known as "Liebig's Annalen," a most invaluable collection of recent experimental discovery. Of his other larger works two more may be mentioned, his "Dictionary of Pure and Applied Chemistry," begun conjointly with Poggendorff and Wöhler, and his "Handbook of Organic Chemistry," a treatise translated into French and English by Gerhardt and Gregory respectively.

Examining the whole "Life Work of Liebig" as put before us in this admirable discourse of Prof. Hofmann, the reader must be at once struck with the enormous amount of work which it is almost impossible to believe could have been accomplished by one man during a lifetime. The number of his papers published in the records of the Royal Society alone is, we are told by Prof. Hofmann, 317, of which 283 are by Liebig himself, the remainder published in conjunction with other chemists. It is worthy of remark, however, that from the number and ability of the pupils he drew around him, Liebig was able to trust certain of his researches to their care, invariably, however, giving his assistants all credit for any ideas or discoveries of their own.

If Liebig was followed ardently by his pupils it was because he possessed the rare gift of inspiring them not only with admiration but with love. With the spirit which was equally characteristic of Faraday's genius, Liebig endeavoured to lead his followers beyond mere single spheres of thought to the conception of laws regulating wide ranges of phenomena, tending in their results to the material welfare of mankind.

We feel sure that this interesting account of the work of one so distinguished and widely known as Justus Liebig, will be read with great pleasure not only by chemists but by all who are interested in the progress of natural science.

JOHN M. THOMSON

HUNTING-GROUNDS OF THE GREAT WEST

The Hunting-Grounds of the Great West, a Description of the Plains, Game, and Indians of the Great North-American Desert. By Richard Irving Dodge, Lieut.-Col. U.S.A. With an Introduction by William Blackmore. (London: Chatto and Windus.)

MR. WILLIAM BLACKMORE, well known to anthropologists in connection with the Blackmore Museum at Salisbury, hunted buffalo on the great plains of the Far West with Col. Dodge. The American colonel's camp-fire stories seemed to his English companion well worth preserving, and thus the present volume came to be written, and dedicated to Mr. Blackmore, who has prefaced it with an introduction on the Indian tribes of North America and the causes of their extinction. No doubt Mr. Blackmore was right in encouraging his friend to write his book, which contains much curious information not got up out of other books, but drawn direct from life in the Indian country, and told well in barrack-room fashion. The bold picturesque illustrations by Griset suit the contents well, and the volume in its red and gold binding might have been recommended as a gift-book, had the author had the discretion and good taste to exclude certain stories as to the relations of the sexes among Indian tribes, as well as several pages of revolting details respecting the fate of those who fall as captives into the hands of such tribes as the Comanches, which ought not to have found a place in it.

In pointing out that these contents must in great measure remove the book from popular circulation, we do not say that they should not have been printed somewhere, though a smart *ad captandum* volume was not the proper place. In fact they form part of a general description of Indian society, which students of the development of law and morals may read with considerable advantage. The necessary growth of some rule of female propriety in societies where the women are the absolute chattels of the men, is illustrated with remarkable clearness among the Cheyennes (see p. 301, &c.), and all the more plainly by contrast with the habits of their husbands, who, being no one's property, own no social restraint whatever. Again, however brutal the individuals of any tribe may be, there must be a social contract observed or the whole society would collapse. This also is well shown among the Cheyennes, by the fact that women obtain absolute protection by a merely symbolic form, which, if any man failed to respect, he would certainly be killed (p. 303). Again, the existing marriage law of the Cheyennes (p. 300) furnishes an instructive commentary on the story of King Gunther's marriage with Brynhild in the Nibelungen Lied, which is possibly a relic of Germanic custom in remote barbaric times. These are a few among many points in which modern savage society throws light on the ancient manners of nations now in the front ranks of culture.

The state of the savage mind as contrasted with that of the civilised man is well brought out in the following remarks by Col. Dodge as to what will and what will not astonish an Indian:—

"The Indian has actual and common experience of many articles of civilised manufacture, the simplest of which is as entirely beyond his comprehension as the most complicated. He would be a simple exclamation-point did he show surprise at everything new to him, or which he does not understand. He goes to the other extreme, and rarely shows or feels surprise at anything. He visits the States, looks unmoved at the steamboat and locomotive. People call it stoicism. They forget that to his ignorance the production of a glass bottle is as inscrutable as the sound of the thunder. A piece of gaudy calico is a marvel; a common mirror a miracle. He knows nothing of the comparative difficulties of invention and manufacture, and to him the mechanism of a locomotive is not in any way more matter of surprise than that of the wheelbarrow. When things in their own daily experience are performed in what to them is a remarkable way, they do express the most profound astonishment. I have seen several hundreds of Indians, eager and excited, following from one telegraph pole to another a repairer, whose legs were encased in climbing boots. When he walked easily, foot over foot, up the pole, their surprise and delight found vent in the most vociferous expressions of applause and admiration. A white lady mounted on a side-saddle, in what to the Indian women would be almost an impossible position, would excite more surprise and admiration than would a Howe's printing press in full operation" (p. 309).

Both Mr. Blackmore and Col. Dodge lament over the wanton destruction of the buffalo in the hunting-grounds of the Far West, where they are killed by tens of thousands merely for the value of their hides. On the Arkansas River, where the hunters had formed a line of camps, and shot the buffalo night and morning when they came down to drink, Mr. Blackmore found their putrid carcases in a continuous line along the banks (p. xvii.). He reckons that in three years as many buffalo have been thus wastefully slaughtered as there are cattle in Holland and Belgium, and the map prefixed to the book shows the insignificant patches to which the buffalo ground, in 1830 extending across the whole middle of the continent, had shrunk by 1876. How recklessly the extermination was carried on may be judged from the description, at p. 137, of the "great buffalo-skinner's" method of using a waggon and horses to take the hide off the carcase at one pull, the ordinary method of careful flaying being found too slow. The destruction of the buffalo, driving the tribes of hunting Indians to starvation and revolt, has done much to hasten the extinction of this doomed race. But it is not the only cause of their destruction so swiftly going on. Every one who reads the details here given as to how the Indians carry on their war against the white settlers, must see that the whites will inevitably pursue the policy of killing them down till only a helpless remnant survives. But every candid reader will agree with Mr. Blackmore and Col. Dodge that it is the ill-treatment of the settlers, and the faithless disregard of Indian treaties by the American Government, that have made the warrior tribes into human wolves. It is evident that a humane while firm policy might have given the Indian tribes at least some generations of existence and well-being. We English have much to reproach ourselves with as to the treatment of indigenous tribes, but in Canada these have not fared quite so ill as in the United States. Indeed, Mr. Blackmore shows by American testimony that the comparatively prosperous condition of the Indian tribes in the British possessions is due to our more just and kindly management of them. But their prospects look hopeless enough in such districts as Idaho, in United States territory, where the legislature could put forth the following proclamation of reward to men who go "Indian hunting":—"That for every buck scalp be paid $100, and for every squaw $50, and $25 for everything in the shape of an Indian under ten years of age."

Col. Dodge's chapter on "Travel" contains an interesting description of the branching ravines which intersect the table-land of the western plains, where valley-systems, with their numberless tributaries, often approach one another so as to be only separated by narrow "divides." Such a region presents interesting problems of valley-excavation to the geologist, but extraordinary difficulties to the path-finder, who, though his destination may be but a few miles off in the straight line, has to find and follow the divide, often in a circuitous track of as many leagues, that he may avoid a score of deep ravines which cut the ground between. Going up divides is easy enough, for they all must reach the principal, or summit, divide; but in going down, the one practicable divide has to be selected from hundreds which at the top look just as practicable to the waggoner, but only lead him, with his loaded wains, down upon the tongue of land in the fork of two steep ravines, where he must turn back and try again. Where there are buffalo, their trail marks the proper route, but otherwise the intricate maze can hardly be threaded except with the aid of an Indian guide or a perfect map. An account of these valleys, with a sketch like the author's, should find its way into every book on physical geography.

OUR BOOK SHELF

The Combined Note-book and Lecture Notes for the Use of Chemical Students. By Thomas Eltoft, F.C.S., &c. (London: Simpkin, Marshall, and Co., 1876.)

MR. ELTOFT is, we see from his title-page, engaged in teaching chemistry to two very large evening classes and also to the matriculation class at St. Bartholomew's Hospital, he has therefore very considerable experience as to the kind of instruction required by students going up for examination either to the University of London matriculation examinations, or to those of the Science and Art Department. His knowledge of the wants of the students has no doubt led him to the production of the "Note-book" we have before us; and we do not doubt that the system here followed will save the student much trouble otherwise incurred in wading through his own notes, so often ill arranged, and missing the salient points of the lecture.

The first twelve pages of the book following the index are occupied with a mass of useful memoranda, as we should prefer to call them, such as notes on formulæ, atomic weights, nomenclature, use of numbers, brackets, and signs, &c., in formulæ; the construction of constitutional formulæ, the base saturating power of acids, the density of gases, calculation of formulæ from analyses, and that tremendous crux with the ordinary student, the crith.

Of course the book is not intended for regular science students such as attend the Royal College of Chemistry and other science schools, but rather for those who take up chemistry either as a branch of general education or as an evening study, and for this purpose it seems to be well fitted; at the same time there is the danger of cram to be guarded against. The author evidently feels this and has endeavoured to provide against it in a somewhat original manner. Pages 102–121 are divided into double columns, the left hand one on each page containing the preparation or reaction formulæ of one of the non-metallic elements and their more simple compounds; the right hand column is left blank, and the student is requested to note the conditions under which each substance is prepared either from the lecture or from a text-book. This device would if conscientiously carried out by the teacher, probably prevent cram of a certain sort, and compel the student to know a little more than the mere formula of a reaction or preparation. At the same time we must confess that we must still regard this knowledge as only another form of cram which is infinite in its varieties and made to suit the idiosyncrasies of each individual examiner, and which will exist as long as any form of knowledge continues to be looked on as something to "pass" an examination in; and as long as examiners continue to look only to a set of answers given on a certain day in a certain time to a particular set of questions, and not to the general character and capacity of the student. We therefore think that Mr. Eltoft will meet with failure in his well-meant effort; we trust, however, that he will continue to persevere.

The rest of the book is divided into double pages, meant for notes on particular elements, the pages being divided according to a scheme in which specific gravity, in the state of solid, liquid, or gas, colour, melting-point, and boiling-point, are successively considered. Another space is reserved for the description of the experiment, a third for sketches of apparatus, and a fourth for tests for the identification of the body. These pages will no doubt teach the student to systematise his notes to a very considerable extent and indicate to him a detailed method of observation.

In conclusion, we note that Mr. Eltoft, in his short preface, expressly states that his "note-book" is "not in any way supposed to take the place of a text-book, but to act as an adjunct to it." We regard it in this light as an honest effort to assist the large class of students for whom it is intended, and we hope that the author will watch the effect of the book on the classes he is teaching, look on his present effort as experimental, and come forward again with the aid of his increased experience to still further improve his work.

R. J. FRISWELL

LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.]

Solar Physics at the Present Time

IN reference to Prof. C. P. Smyth's letter in NATURE, vol. xv. p. 157, I think it my duty to state that Prof. Smyth's remark on the priority of his exhibited results of observations of deep-sunk thermometers (as bearing on the question of transmission of waves of temperature into or from the interior of the earth) is perfectly correct.

It was only in the last summer that, having occasion to inspect some parts of Prof. Smyth's printed "Observations," I became acquainted with the extensive series of diagrams illustrating this matter. I have not yet been able to refer to his cited paper in the "Philosophical Transactions." G. B. AIRY

Royal Observatory, Greenwich, S.E.,
1877, January 1

Just Intonation, &c.

UNDER this heading your correspondent "A. R. C.," while explaining Mr. Colin Brown's "natural finger-board," writes thus:—"The vibration numbers of the diatonic scale being represented by—

$$1,\ \frac{9}{8},\ \frac{5}{4},\ \frac{4}{3},\ \frac{3}{2},\ \frac{5}{3},\ \frac{15}{8},\ 2.$$

If we build upon the dominant $\frac{3}{2}$, the vibration numbers will be—

$$1,\ \frac{9}{8},\ \frac{5}{4},\ \frac{45}{32},\ \frac{3}{2},\ \frac{27}{16},\ \frac{15}{8},\ 2,$$

and if we build upon the subdominant $\frac{4}{3}$ the vibration numbers will be—

$$1,\ \frac{10}{9},\ \frac{5}{4},\ \frac{4}{3},\ \frac{3}{2},\ \frac{5}{3},\ \frac{16}{9},\ 2."$$

Unless "A. R. C." proposes some new system of tuning, I submit that he is in error in the first steps of his two examples. The dominant of C is G, and from G to A is a minor, and not a major, tone. Also the subdominant to C is F, and from F to G is a major, and not a minor, tone. I do not pursue the analysis, not desiring to criticise oversights, but to draw attention to a not uncommon misconception of the figures in the above scale, and to the general adoption of a miscalculation as to the so-called "Comma of Pythagoras."

An eminent mathematician, not long deceased, derived our diatonic scale from the one note F, by the following process:—"F A C—C E G—G B D," thus taking the common chords of three different keys. Had he followed out his system of adding on a new scale from the Fifth of the preceding, he would have gone the round of the keys, and have derived them all from F, which would have been the *reductio ad absurdum*.

Nothing can be clearer than the history of the scale, and it carries with it conviction of its truth. The octave was formed out of two Greek conjoined tetrachords, such as B C D E and E F G A, the E being common to both. Then the lower A was added at the bottom, to complete the octave, and it was called "the added note" (*proslambanomenos*) because it did not form part of any tetrachord. The reduction from the eight notes of the two tetrachords to seven is attributed to a superstition in favour of the number seven. Thus came our A B C D E F G A—a minor scale with a minor Seventh—and from it came our truer major scale, by commencing on the third note, C, but carrying with it all the imperfections of the double root of the original. No improvement has been made in the scale since the days when Archytas, the friend of Plato, introduced the consonant major Third, and Eratosthenes the minor Third. Our present scale is therefore absolutely anterior to the Christian era; the ratios of its intervals given by Greek authors prove the identity irresistibly. Let us then look to the figures which represent our scale as "A. R. C." has justly given them. The large 1 and 2 refer to C as the fundamental note and its octave. The 3 to 2, the 5 to 4, the 9 to 8, and the 15 to 8 represent octaves of the key-note (2, 4, or 8); but the 4 to 3 (the interval of a Fourth) and the 5 to 3 (the interval of a major Sixth) refer to C only as the so-called "Twelfth" above F, and not to C as the octave. If we play either of these two notes, F or A, with C, we cannot use C as a consonant bass. We must take F, and thus we have the old tetrachord system, with its double root, running in our present scale. In all keys the tonic and the subdominant are both necessary basses. F and A belong exclusively to F; but B and D have no relation to F, not being aliquot parts of the F string. They belong to the scale of C, but more intimately to that of G. The F string exceeds the length of the C string by 3 to 2, because its sound is that of a Fifth below C; therefore any attempts to bring the sounds of our scale to a common denominator are fallacious, the first law of Proportion being that "Ratio can subsist only between quantities *of the same kind.*" Thus the "24, 27, 30, 32, 36, 40, 45, 48," cannot be accepted, because the 32 intended for the 4 to 3 of the scale, and the 40 for 5 to 3, represent other intervals. The 4 to 3 of C is the Fourth from C down to G, and the 5 to 3 of C is the major Sixth from E down to G. The 32 and 40 are not applicable to the interval of a Fourth from F down to C, nor to the major Sixth from A down to C.

And now as to the so-called "comma of Pythagoras," a strange name for the interval of 531441 to 524288! Can the modest inventor, who has concealed his own name, have supposed that the Greeks had musical instruments so very far beyond the compass of our seven or eight octave grand pianofortes? This interval is simply the excess of the twelfth power of 3 over the nineteenth power of 2. As powers of 3 are Twelfths, in music—octaves with Fifths, and not merely Fifths—and as octaves are powers of 2, this comma represents B sharp as topping C in its *nineteenth* octave. Happily any nineteenth octave is beyond our powers of hearing, even if we adopt a No. 1 with only one vibration in a second of time. We may therefore dismiss so disagreeable a sound to the so-called "Music of the Spheres," in compliment to Pythagoras, who is supposed to have been acquainted with music of that kind.

We are too generally prone to rely upon the labours of our predecessors, and hence this peculiar comma has been received without examination, as the overlapping of twelve Fifths over seven octaves, as stated by "A. R. C." After having traced what it really is, wishing to find the author of the miscalculation, I took up a newly-acquired copy of Koch's "Musikalisches Lexicon," which, although written in the last century, is still reputed as a work of authority, and has been re-edited by Arrey von Dommer (8vo, Heidelberg, 1865). I found a more curious mistake: instead of twelve Fifths, it is there stated to be twelve Fourths *or* Fifths; and Koch's way of proving it is by multiplying the ratios, not as fractions, but as whole numbers. For example, a Fifth and a Fourth we know to make one octave, but Koch multiplies 3 times 3 = 9 in one column, and 4 times 2 = 8 in the other (p. 24). As the twelve threes are in one column, he arrives by multiplication at the twelfth power of 3, and as the fours and twos are in the other column, he arrives at the nineteenth power of 2. It is desirable that this should be known as a caution against too-ready acquiescence in Koch's calculations.

WM. CHAPPELL

On "Comatula (Antedon) Rosacea," and the Family "Comatulidæ"

MAY I be allowed to point out to Mr. Stebbing that *Comatula* and *Antedon* are not precisely equivalent names, but that the genus *Antedon* represents only one of some five or six different types, to all of which "Lamarck's happily appropriate designation *Comatula*" is equally applicable; and that this is now generally used as a sort of family name, and only when strict scientific accuracy is not very important, as a generic name.

Johannes Müller, who laid the foundation of nearly the whole of our present knowledge of the zoology and morphology of the family, was the first to recognise that Lamarck's designation, *Comatula* included more than one type; in his well-known memoir, "Ueber die Gattung *Comatula*, Lamarck, und ihre Arten," he indicated two distinct varieties of *Comatulæ*, the one represented by the ordinary *Comatula rosacea*, with a central or subcentral mouth, and symmetrically distributed ambulacral furrows; and another, which he first recognised in the ordinary *Comatula solaris*, Lamarck, to which he gave the name *Actinometra*: in this type the mouth is marginal, and the furrows of the ten arms open at equal intervals into a circular furrow running round the edge of the disc, the centre of which is occupied by the anal tube. The first of these types is that to which de Freminville's name of *Antedon* is now usually applied. Müller, however, seems never to have been acquainted with this name, and adopted Leach's genus *Alecto*, which was constituted three years subsequently to *Antedon*; while *Comatula* did not appear till a year later. Recent observations have, however, shown that *Alecto*, as used by Müller, really includes many forms that are true *Actinometræ*, and the name has passed gradually into disuse, in its original application to the Crinoids; this was all the more necessary, as the name has been generally received as designating a genus established by Lamouroux in 1821, for a section of the Polyzoa.

Müller was in the habit of using a sort of trinomial nomenclature in his descriptions of the species of *Comatula*; thus, *Comatula* (*Alecto*) *europæa*, and *Comatula* (*Actinometra*) *solaris*; it will probably be advisable to continue this practice, and it is therefore somewhat unfortunate that Mr. Norman[1] should have transposed *Antedon* into a masculine name, for de Freminville, who first proposed it, used it as a feminine one, and described his first and only species as *Antedon gorgonia*, which is probably the same as *Comatula carinata*, Lam. Pourtales has already adopted *Antedon* as a feminine name, and we should probably do well to follow his example, especially if we employ Müller's very convenient system of trinomial nomenclature, for it is far simpler to write *Comatula* (*Antedon*) *rosacea*, than *Comatula rosacea* = *Antedon rosaceus*.

Besides these two types *Antedon* and *Actinometra*, there is, as Müller pointed out, another division of the *Comatulæ* represented by the recent *Comnster* of Agassiz and the fossil *Solanocrinus* of the Wurtemburg Jurakalk; these are distinguished from the ordinary *Comatulæ* by the fact that five small basals appear externally between the first radials. The five small ossicles lying between the second radials of *Antedon Dübenii*, Böhlsche, are possibly also external basals. It is unfortunate that Böhlsche was unable to make a further examination of this species, and so determine this very interesting point.

Müller considered *Solanocrinus*, or at any rate *S. costatus* and *S. scrobiculatus* as generically identical with *Comaster*, and pointed out that the differences in the form of the "knopf," or centrodorsal basin, which is elongated and more or less fusiform in *Solanocrinus*, and hemispherical in *Comaster*, could not be regarded as of generic value, for similar differences occur among different species of the recent *Comatulæ*; *e.g.*, between *C. Eschrichtii*, Müll. and *C. phalangium*, Müll. I have recently found that such differences may occur within the limits of the same species. Thus, of the two specimens of *Comatula* (*Antedon*) *macrocnema* in the Paris museum, one has a hemispherical centrodorsal basin, just like that of *Comatula* (*Antedon*) *Eschrichtii*,, while in the other it is a short pentagonal or nearly circular column, on which the cirrhi are disposed in four alternating rows, precisely as in *Solanocrinus*. Götte, who has recently made some most beautiful observations upon the embryology of *Comatula*, opposes the view first suggested by Sir Wyville Thomson, and since adopted and strengthened by Dr. Carpenter, that the centrodorsal basin represents a coalesced series of the nodal or cirrhus-bearing stem-joints in the stalked Crinoids, but its condition in *Solanocrinus* and *Antedon macrocnema* seems to show unmistakably that Sir Wyville Thomson's determination of its homologies is the correct one, especially when it is remembered that, as Goldfuss says, young specimens of *Solanocrinus* are not uncommon, in which the articular surfaces of the segments composing the elongated "knopf" are visible, although in the adult animal they become so closely united as to be inseparable.[1]

Unfortunately we do not know the position of the mouth in *Comaster*, the only specimen yet known having been dissected by Goldfuss, who says little or nothing about the ventral surface; but in *Phanogenia*, a new genus of the free Crinoids established by Lovén, it is central, as in *Antedon*.

These four types, *Antedon*, *Actinometra*, *Comaster*, and *Phanogenia*, all currently regarded as belonging to Lamarck's genus, *Comatula*, differ very considerably from one another in many points, perhaps the most characteristic of which is the condition of the basals in the adult animal.

In *Antedon*, as shown by Dr. Carpenter, the primitive basals of the Pentacrinoid larva undergo a very remarkable metamorphosis into the small and relatively insignificant "rosette;" this is almost entirely inclosed within the circlet of first radials, with which it becomes more or less fused in the adult animal, and by which it is so concealed as very readily to escape notice; so that all the older investigators either denied the existence of basals at all, or like Goldfuss, mistook the first radials for basals. I have recently found that in *Actinometra solaris* (Müller's typical species), and in several other species of the genus, the basals are relatively very large, and take the shape, not of a "rosette," but of a five-pointed star, the rays of which lie on the dorsal aspect of the five sutures of the first radials with one another, while its centre is simply an open and very delicate calcareous network, more or less connected with that proceeding from the inner surface of the radial circlet. These basals are readily exposed by the removal of the flattened centrodorsal basin, the ventral aspect of which exhibits five stellate interradial depressions, into which the basals fit, but they never extend outwards so far as to be visible externally.

This last condition, of external basals, occurs, however, in *Comaster*, and in the Jurassic *Solanocrinus*. The centrodorsal basin of *Comaster* is hemispherical, and round its ventral margin lie five small triangular basals, not in contact with one another, but so widely separated that the first radials lying between them articulate directly with the centrodorsal basin, while their inferolateral angles are truncated so as to make room for the intervening basals.

---

[1] "On the Genera and Species of British Echinodermata," Ann. Mag. N. H., xvi, 1865.

[1] Further, in the singularly minute *Comatula alticeps* found by Philippi between the valves of a fossil *Isocardia cor* from the Sicilian Tertiaries, the centrodorsal, which he calls the "kelch stück," is elongated, egg-shaped, and visibly composite, bearing at least two, and very probably several more, alternating rows of cirrhi just like that of *Antedon macrocnema*. I have little doubt but that this species was a true *Antedon*, and an ancestor of our recent *Antedon rosacea* which is now so common in the Mediterranean.

The basals of *Phanogenia* appear to be in a condition intermediate between that of *Antedon* and *Actinometra.* Lovén describes them as internal and concealed, forming a small rosette with a central pentagonal opening, and marked on its ventral face by five sinuses, which receive processes from the sutures of the first radials.

We have thus a very interesting series of transitions from *Antedon* to *Pentacrinus*; firstly through *Phanogenia* and *Actinometra* to *Comaster*; thence to *Solanocrinus costatus*, in which the basals resemble those of *Comaster*, but the centrodorsal basin is elongated and visibly composite; and finally to *S. jægeri*, Goldfuss, in which the basals are so wide that they are completely in contact with one another all round, precisely as in *Pentacrinus*; this genus then only differs as far as the stem and basals are concerned, from *S. jægeri*, by the fact that its nodal cirrhus-bearing stem-segments are not fused together, but separated from one another by more or fewer of the internodal ones which do not bear cirrhi.

Solanocrinus thus constitutes, as already pointed out by Goldfuss, a very interesting intermediate form between the stalked *Pentacrini* and the ordinary free-living *Comatulæ*, which are only stalked in their young stages.

Besides the above-mentioned four generic types, or rather five, if Pictet be right in erecting *S. jægeri* into a separate genus, Lamarck's name *Comatula* also includes the beautiful little five-armed *Ophiocrinus* from the Philippines; unfortunately we do not yet know either the condition of its basals or the anatomy of its soft parts, and can therefore form no opinion as to its relations to the other members of the family.

As these five or six types are all equally entitled to the name *Comatula*, it becomes necessary in any systematic work on the family to give them distinct generic or sub-generic names, especially as in one or two cases the same specific name has been given to two or more types. Thus the *Comatula multiradiata*, Goldfuss, is a *Comaster*, while the *C. multiradiata* of Lamarck is an *Actinometra*; and again the *C. armata* of Pourtales is an *Antedon*, while *C. armata*, Semper, is an *Actinometra*.

For ordinary dredging work, however, on the British coasts, where *Antedon* is the only representative of the family, it is not so necessary to discard a common and better known name in favour of one which, although scientifically correct, and considerably older, has only recently come into general use, especially when, as Mr. Stebbing remarks, its meaning and pronunciation are alike difficult to determine; and though the designation *Comatula rosacea* may, scientifically regarded, be a somewhat loose one, it is now so well known that the use of it is not likely to lead to any serious mistakes in synonymy among working naturalists. P. HERBERT CARPENTER

Würzburg, Bavaria

WITH reference to the names Antedon and Comatula, will you allow me to say that the former has been applied to a genus of lamellicorn beetles since the year 1832? Comatula has been in use from nearly the beginning of the present century, and it is not only found in the works of Fleming, Forbes, Sars, Owen, G. H. Lewes ("Seaside Studies"), Carus, and others, but it must be a familiar word to many who have seen the splendid tank of those crinoids in the Naples aquarium. And now that we are bidden to change it "on the grounds of priority," may we inquire if the "grounds" of long custom (in this case more than sixty years) are to be invariably set aside? Dr. J. E. Gray, who had a sort of mania for change, tried in 1848 to restore de Freminville's name of Antedon. He went a step further, and, after Pennant, adopted Linck's specific name (so far as Linck had any idea of specific names, for they were unknown in his day) of "decameros," so that the advocates of *absolute* priority will have to take "*Antedon decameros*" as the designation of *Comatula rosacea*.

In Gemminger and von Harold's "Catalogus Coleopterorum," Antedon is derived from ἀντὶ and ὀδὼν, and consequently spelt Antodon; I do not see its application in either case.

I should be glad to see the "rules of zoological nomenclature" (Mr. Hughes means, I presume, those of the British Association) better observed if it led to the exclusion of such barbarisms as Butzkopf, Gatyghol, Sing-sing, Nabiroup, and others, which many of the readers of NATURE will probably be astonished to find in our modern scientific nomenclature. May we inquire if such a description as that of the celebrated "*Hister australis*," viz., "nigro-cyaneus, nitidus, subtus ater," which would apply to hundreds of species of Histeridæ, is entitled to claim the protection of the law of priority? I think we may sometimes fall back with advantage on the law of common sense, or that, at any rate, it may be allowed to supplement the law of priority. FRANCIS P. PASCOE

December 23, 1876

Sea Fisheries

MY chief reason for again intruding on you is for the purpose of supplying some omissions in Prof. Newton's quotations from Prof. Baird's first Report. In this Prof. Baird speaks of the destructive agency of the blue-fish. He states that about a million and a quarter of these fishes are caught annually on the New England coast, but that any one who has watched the blue-fish there must feel convinced that not one in a hundred of these fishes is caught; he allows twenty fish of other kinds as being devoured or mangled by each blue-fish daily, and then goes into a calculation of the thousands of millions of fish which must be destroyed by the blue-fish. I am writing this from memory, but I believe I am correct. Prof. Baird then says (I give this *verbatim*), p. 23:—"Indeed I am quite inclined to assign to the blue-fish the very first position among the injurious influences that have affected the supply of fish on the coast. Yet, with all this destruction by the blue-fish, it is probable that there would not have been so great a decrease of fish as at present but for the concurrent action of man."

This, the other cause of decrease, on which Prof. Baird lays great stress, is the numerous traps and pounds along the coast; but in Clause XII. of the same summary from which Prof. Newton quoted, I find the following:—

"As there is reason to believe that scup, and to a less degree other shore-fish, as well as blue-fish, have several times disappeared at intervals to a greater or less extent, within the historic period of New England, we cannot be certain that the use of traps and pounds within the last ten years has actually produced the scarcity complained of. The fact, however, that these engines do destroy the spawning fish in so great numbers renders it very probable that they exercise a decided influence."

Prof. Newton does not speak with his usual scientific precision when he refers only to the cod, and doubtfully to the mackerel, having decreased owing to the scarcity of the alewives—"cod, haddock, and hake" being mentioned in the same paragraph. Nor does it seem to me quite worthy of my friend, in discussing the probabilities of overfishing in the sea, to try to prove his case by bringing forward an instance of overfishing in the rivers leading to a smaller supply of food at a certain season for purely sea fish on the coast, and therefore a decrease in those sea fish.

Dogfish are "predatory and mischievous:" they plunder the nets, and they tear the nets in pieces.

Athenæum Club, December 29 E. W. H. HOLDSWORTH

[Pressure upon our space has necessitated a curtailment of this letter. This correspondence must now cease.—ED.]

The "Sidereal Messenger"

IN NATURE (vol. xv. p. 49), in a notice of Mr. Knobel's "Catalogue of the Literature of Sidereal Astronomy," attention is called to the rarity of the *Sidereal Messenger*. We have, in the library of this Observatory, only one copy of that periodical. I hope, however, soon to be in possession of a few copies of vol. i. If so I shall take pleasure in sending one of them to the Royal Astronomical Society. All of Prof. Mitchel's measures of double stars (about 300) are now in the hands of the printer and will be published before the close of the year. ORMOND STONE

Cin. Obs., September 12

South Polar Depression of the Barometer

MR. CLEMENT LEY, writing in NATURE (vol. xv. p. 157), thinks that the great depression of the barometer throughout the region round the South Pole as compared with that round the North Pole, is "mainly due to superior evaporation in the water hemisphere generally." This seems an inadequate cause, for evaporation must be small in the very low temperatures which appear to be constant at all seasons in high southern latitudes. I am convinced that the cause of the barometric depression round the South Pole is the centrifugal force of the west winds which revolve round the Pole, forming, in Maury's words, "an everlasting cyclone on a great scale." A similar cyclone is formed round the North Pole also, but less perfectly, and consequently the North Polar barometric depression, though decided, is much less than the South Polar. The reason of this difference I believe to be, that the North Polar cyclone is broken up by local air-currents due to the unequal heating of land and sea—a cause which scarcely exists in the South Polar regions, where almost all is sea or snow-covered land. JOSEPH JOHN MURPHY

"Towering" of Birds

IN connection with Mr. Romanes' valuable letter on this subject, the following note may be interesting. Rooks, I am informed, are sometimes killed by means of a paper cone containing birdlime, which is placed in a locality where these birds congregate. The rook inserts his bill and head into the cone; after a little time he rises vertically into the air and then falls dead. My informant—a traveller and sportsman of much experience—considered the upward motion to be due to the obstruction of sight, but the fact, I doubt not, will bear the same explanation as the towering in the case of a wounded grouse.

ARTHUR SUTHERLAND

IF it is of any importance to the question I may state that I have seen the following birds "tower:"—common snipe, fieldfare, wood-pigeon, pheasant, partridge, common Australian duck (*Anas superciliosa*), large Australian white cockatoo, Australian Nankeen night heron, and Australian piping crow. I have shot many thousands of Australian duck, and towering has occurred among them pretty frequently. In one case, the notes of which I have, the duck began to rise almost immediately, and rose to a great height. I was indoctrinated in the cerebral injury hypothesis, but I soon found that this was untenable, for I made a habit of plucking and examining the heads of all towering birds which I could recover, and there were some among them with no wound whatever on the head. One such instance would have been sufficient to dispose of the hypothesis; but I was unable to substitute another for it. The explanation given by Mr. Romanes meets the conditions as far as they have come under my observations. A. N.

THE SOCIETY OF TELEGRAPH ENGINEERS

THE Annual General Meeting of this Society was held at The Institution of Civil Engineers, 25, Great George Street, Westminster, on the evening of Wednesday, the 13th instant.

The Report submitted by the President and Council showed that during the past year the number of Foreign Members, Members, and Associates had gone on increasing until the total of all classes now exceeded 800. Many valuable papers, it was stated, have been sent in, or promised, for discussion during the current session, almost every available evening being already taken up. The result of the ballot for the President, Vice-Presidents, and Council for the ensuing year, was announced, Prof. Abel, F.R.S., being elected President.

A *Conversazione* was held at Willis's Rooms on the evening of Monday the 19th inst., when about 600 were present. Amongst these were to be found almost all the prominent members of the telegraphic profession, as well as most of the representatives of the leading cable companies and men whose names are known in connection with electrical or telegraphic engineering. A magnificent display of apparatus had been got together, including everything in the shape of a novelty which had been introduced in connection with this branch of science during the past year. Many interesting experiments were shown, and for the more especial gratification of the non-scientific portion of the assembly, Mr. Apps and Mr. Browning of the Strand exhibited respectively their attractive vacuum tubes and microscopical objects.

Prominent amongst the features of the evening were the experiments designed and personally exhibited by Mr. Robert Sabine. These may be divided into three classes—(1) Showing the circulation of mercury under the influence of oxidation and deoxidation; (2) Measuring time to the infinitesimal portion of a second; (3) Showing the potential at various points and the speed of waves of electricity through submarine cables. Full descriptions of these experiments—now publicly shown for the first time—have been contributed by Mr. Sabine to the recent numbers of the *Philosophical Magazine*. It was on the first-named that Sir Charles Wheatstone was engaged at the time of his death in Paris, and, based upon the results which he obtained, he had constructed a form of mercury "relay" constituting one of the most delicate portions of receiving telegraphic apparatus that could possibly be devised. The duration of impact, when an anvil is smartly struck with a hammer, was measured by means of the arrangement in connection with the second series of experiments. A condenser is charged from a potential of one volt, and then discharged through a Thomson's reflecting galvanometer, the deflection on the scale being noted. The condenser is again charged; a hammer in connection with one side of it is then brought on to the anvil which is in connection with the other side; during the moment of impact partial discharge takes place, the amount of current escaping being known when that which remains is next measured through the galvanometer. All the factors being thus known, the question of the time during which the hammer and anvil were in contact becomes a matter of simple mathematical calculation. The third series, owing to the difficulty of obtaining a sufficient length of Muirhead's artificial cable, was scarcely so successful as the other two, but yet sufficient was done to show the principle involved.

Prof. Dewar's electrometer, by means of which the electromotive force of the most minute fraction of any galvanic cell may be measured, and which is based upon the oxidation and deoxidation of mercury, was also shown.

Amongst the apparatus Sir William Thomson's new form of marine compass proved to be a centre of attraction. The adjusting "spider"—the most recent addition—was absent, but yet enough was exhibited to show that the mariner might to a great extent now render himself independent of solar observations. Eight small magnetic needles are employed, and the friction of the various parts is reduced to a minimum. Two soft iron balls are placed, one on each side of the compass, and adjusting rods are employed in addition to them. The liquid gyrostat, already described in NATURE, was also amongst Sir William Thompson's collection.

Hanging around the walls of the room were carefully executed diagrams, showing what are perhaps the most valuable observations of earth-currents that have ever been made. They were exhibited and are now presented to the Society by Mr. H. Saunders, of the Eastern Telegraph Company. Availing himself of a broken cable between Suez and Aden, Mr. Saunders succeeded in obtaining simultaneous observations at both stations, and saw that they are graphically represented; the coincidence between the two is striking to a degree. It is to be hoped that so interesting a record as this may be brought prominently forward in the form of a paper, and so elicit a discussion upon a subject which, although occupying the attention of many, still remains one of the most obscure problems in connection with electrical science. Closely allied to these were the specimens of the movements of the declination and horizontal magnetic force and of the earth-currents as observed at Greenwich and sent up specially for the evening by the Astronomer-Royal. They comprised the observations for a calm and a disturbed day, and served to show very clearly the correspondence which exists between magnetic and galvanic disturbances.

A form of grapnel designed by Mr. Andrew Jamieson, assistant to Mr. Saunders, did not fail to attract considerable attention. The toes, instead of being rigid, are hinged on to a spring which yields under a pressure of two tons, and thus serves to release the toes from any rocks or foreign matter with which it may be brought into contact, whilst a hold is still retained of the cable.

A telephone—showing clearly the principle of the apparatus—was exhibited by the Messrs. Wray, and musical notes were accurately transmitted by means of it through about 120 feet of wire. The battery employed for the purpose was the thermopile, designed by themselves, which was also shown. Although at first sight very similar to the well-known form of Clamond, the thermopile of Messrs. Wray has several modifications which are undoubted improvements. The extreme brittleness so fatal to many of Clamond's bars is here got rid of by the introduction, for a distance of about two inches, into the alloy, of a tongue which really is only a continuation of the sheet-iron. At first sight one would be inclined to think that this would tend to lower the electro-motive force of the couple, but the reverse is stated to be the case. The asbestos rings are replaced by a framework composed of circular plates of earthenware supported on three tie rods which serve to give stability to the structure and remove from each ring of bars the superincumbent weight of all the others over it. But perhaps the main improvement effected is the method of heating the bars; instead of allowing the flamers to impinge directly on their ends, or admitting the products of combustion near them, an earthenware cylinder forms the centre of the pile. Around it and abutting hard upon it the bars are placed, and from a perforated chimney within the gas issues, and burning in blue jets, speedily raises the cylinder to a red heat, which is transmitted through to the ends of the bars.

THE PHYLLOXERA AND INSECTICIDES

SOME time ago we published in our columns a short account of the results of the investigations of various scientific men in France into the nature of the Phylloxera—that terrible scourge which is committing such widespread ravages among the French vineyards. Latterly we have received some reports communicated to the French Academy of Sciences dealing with the attempts which have been made during the last three or four years to arrest the mischief done by the insect, and ultimately to destroy it altogether, by means of some potent drug. It is obvious that the remedy to be employed must possess two qualities at starting, viz., it must destroy the insect and it must not damage to any great extent the vine. But, further, it is not sufficient that when put in close contact with the roots of a plant—as in a pot—it should prove fatal to the insect, it is necessary, if the remedy is to be of real practical value, that it should reach and destroy the Phylloxera on all the parts attacked by it in vines which are planted out in the open air. This is a real difficulty to overcome, as the remedy, be it in the form of solution or of vapour, cannot easily permeate the soil, sometimes clayey, sometimes sandy, on which the vine is growing, so as to reach and act upon the smaller root branches whose nutrition the Phylloxera diverts into itself.

M. Mouillefert, a professor at the School of Agriculture at Grignon, was the gentleman delegated by the Academy of Sciences to make the necessary experiments for the purpose of determining what agent was the most practically applicable to the destruction of the Phylloxera, and the account of the numerous substances employed by him with varying results fills no less than 200 pages of a memoir presented to the Academy of Sciences. It is not our intention here to do more than give a brief *résumé* of the results at which he arrived.

He divides the substances used by him into seven groups, the first of which was composed of manures of various kinds, such as guano, superphosphates, farm-muck, &c.; the second of neutral substances, as water, soot, and sand; the third of alkalies, as ammonia and soda; the fourth of saline products, amongst which were the sulphates of iron, copper, zinc, potassium, and ammonia, alum, and sea-salt; the fifth of vegetable essences and products, as decoctions of hemp, datura, absinthe, valerian and tobacco; the sixth of empyreumatic products; and the seventh of sulphur compounds. It was only with some of the substances contained in this last group that really satisfactory results were obtained, and it is to M. Dumas, the permanent secretary of the French Academy of Sciences, that the credit is due for suggesting the employment of the alkaline sulpho-carbonates of potassium and sodium and those of barium and calcium. All the other classes of remedies mentioned above were either without effect on the Phylloxera, or, in destroying it, also destroyed or damaged the vine.

The sulpho-carbonates, which were carefully studied by the great Swedish chemist Berzelius, are obtained by combining the alkaline mono-sulphides with the bi-sulphide of carbon, are either liquid or solid, and emit a powerful odour of sulphuretted hydrogen and bi-sulphide of carbon.

The alkaline sulpho-carbonates in the solid state are of a beautiful reddish yellow colour and deliquescent, but are not easily obtainable in that condition; the sulpho-carbonate of barium can be easily procured, however, in a solid state, and presents the appearance of a yellow powder, but little soluble in water. The sulpho-carbonates decompose under the influence of carbonic acid, forming a carbonate, and evolving sulphuretted hydrogen and bi-sulphide of carbon. These two latter substances are gradually liberated and, as they have a very powerful effect on the Phylloxera, one can understand that the sulpho-carbonate, placed in the ground, may prove, by its slow decomposition, a powerful insecticide. In the case of the sulpho-carbonate of potassium, over and above its toxic effect, it has a direct invigorating influence upon the vine, as the carbonate of potassium is an excellent manure.

The employment of the sulpho-carbonates as a means for the destruction of the Phylloxera was suggested to M. Dumas by the clearly-recognised need that there was of some substance that would evaporate less quickly than the bi-sulphide of carbon; he saw that it was desirable to apply the insecticides in some combination which would fix them and only allow them to evaporate gradually, so that their action might continue long enough in any one place to infect with their vapours all the surrounding soil.

But the task of eradicating the Phylloxera has by no means been accomplished by the mere discovery of the value for the purpose of these substances; there is the further difficulty of applying them to the vine in cultivation. One thing seems very certain, that in order to render the sulpho-carbonates practically efficacious in killing the insect, it is necessary to use water as the vehicle by which they may be brought to all the underground parts of the plant, and that the best time of year for their application is the winter or early spring, when the earth is still moist and the quantity of water necessary to be brought on to the ground by artificial means is consequently less. Mixed with lime in the proportion of 2 to 1, these sulpho-carbonates give a powder which can be spread over the ground before the heavy rains, that is, between October and March, and which will probably prove itself very efficacious.

The conclusion at which M. Mouillefert arrives at the end of his report is that the efficacy of the sulpho-carbonates is proved, and all that is necessary is to bring to perfection their employment in agriculture, which can only be accomplished by the intelligence and practical knowledge of the vine-grower who is well able to discover the economic processes of culture which are conducive to their successful application.

He ends by saying that "Science has accomplished its mission, and it remains for Agriculture to fulfil its part" in the eradication of the Phylloxera from the vineyards of France.

CAMBRIDGE (U.S.) OBSERVATORY

IN two previous articles (NATURE, vol. x. pp. 186, 206) we gave a sketch of the history of some of the principal observatories of the United States. Those which we then referred to are all more or less connected with the work of education. We shall now give some details of an observatory which has been enabled to make marked advances in independent research outside of its educational service; we refer to that of Cambridge, Massachusetts.

A look into the earlier annals of the observatory of Harvard repays the inquirer at the outset by revealing the interest in astronomical pursuits which was felt in the old Bay State many years before the founding of an observatory was practicable in the United States. In 1761 the *Province* sloop was fitted out at the public expense to convey a Harvard professor, Winthrop, to Newfoundland, to observe the transit of Venus of that year; and in the troublous times of 1780 the old "Board of War" fitted out the *Lincoln* galley to convey Prof. Williams and a party of students to Penobscot, to observe a solar eclipse. At so early a day was New England disposed to encourage scientific observations.

In 1805, Mr. John Lowell, of Boston, was consulting with Delambre in Paris on astronomical observatories, and forwarding his information to the Hollis professor, Webber, who even then indulged the hope of seeing an observatory founded. But it was only in 1839 that an observatory was erected on the Dana estate, and the observations which had been authorised by the United States Government to be made in connection with Lieut. Wilkes's exploring expedition were conducted by Prof. Bond until the year 1842.

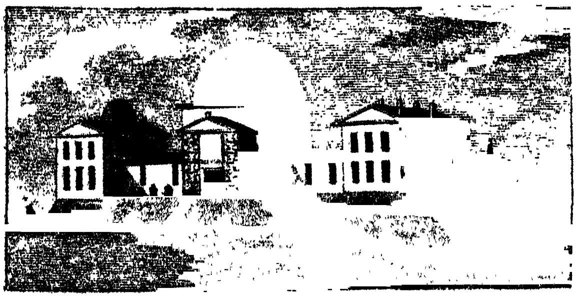

FIG. 1.—Cambridge Observatory.

A new issue now arose. The sudden appearance of the splendid comet of 1843 was, happily, the occasion of final success in the founding of the present institution. Cambridge was immediately appealed to for information about this strange comet. But the observers had no parallactic instruments or micrometers of the least value for its observation. While they were endeavouring to obtain data to compute the comet's orbit, a meeting of citizens was held, under the sanction of the American Academy, to take measures for procuring a first-class equatorial; the needed amount of $20,000 for the instrument was contributed in Boston, Salem, New Bedford, and Nantucket. The equatorial was ordered from Merz and Mähler, of Munich, and Harvard determined to erect a new observatory. The location selected was 80 ft. above tide-water, and 50 ft. above the plain where the soil was found favourable for the stability of piers for the instruments. In 1844 the buildings were occupied, and an equatorial of 44 in. focal length and 2½ in. aperture, and a transit instrument loaned by the United States, were temporarily mounted for observations until the arrival of the great refractor. This was placed in position June 24, 1847. Among the earlier objects on which systematic observations were made with the new instrument were the nebulæ of Andromeda and Orion. "These nebulæ," said Prof. Bond, "were regarded as strongholds of the *nebular theory*; that is, the idea first suggested by the elder Herschel of masses of matter in process of condensation into systems." Orion's nebula had not yielded to either of the Herschels, armed even with their excellent reflectors, nor had it shown the slightest trace of resolvability under Lord Rosse's 3 ft. reflector. Bond announced, on Sept. 27, 1847, that the Cambridge refractor, set upon the trapezium under a power of 200, resolved this part of it into bright points of light, with a number of separate stars too great to be counted. With a power of 600, "Struve's Companion" was distinctly separated from its primary, and other stars were seen as double.

Within a few years yet more brilliant discoveries followed. Among them the inner ring of Saturn and its eighth satellite, the coincidence of which latter discovery on the same day (Sept. 19, 1848) at Cambridge and in England in no wise detracted from the honour due to each discoverer. It required, in those times, weeks before the discovery, indeed, could be mutually made known.

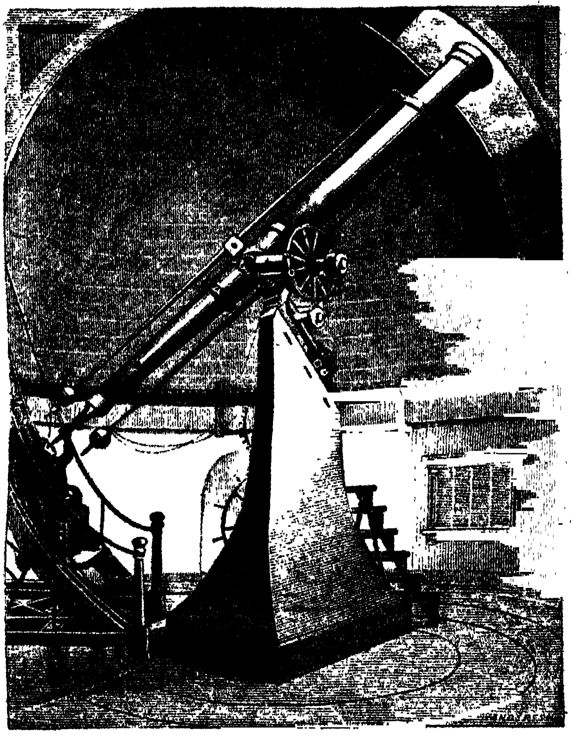

FIG. 2.—Cambridge Equatorial.

In 1850 Prof. W. C. Bond, with his sons, invented the spring governor, which gave an equable rotatory motion to the revolving cylinder of the chronograph. The observatory having been placed in 1849 on a permanent endowment by a legacy of $100,000 from Mr. E. B. Phillips, a young graduate of Harvard, and a fund for printing its results having been also provided by will of the Hon. Josiah Quincy, jun., the reports of the first systematic zone observations appeared in 1855 as Part II. of vol. i. of the "Annals." This zone catalogue comprises 5,500 stars situated between the equator and 0° 20′ north declination. The second volume, published in 1857, embraced chiefly observations of the planet Saturn made during a period of ten years. The second part of this vol. ii. is a zone catalogue of 4,484 more stars in the same zones as those observed before 1854. It was not printed until the year 1867. The splendid vol. iii., published in 1862, is a quarto of 372 pages, with fifty-one plates almost entirely illustrative of the great comet of the Italian astronomer Donati, which appeared in such different forms in America from those seen in England.

The Great Nebula of Orion was the other chief object of the observatory up to the death, in 1849, of Prof. W. C. Bond, the father, and thence to the death of the son, Prof. G. P. Bond, in 1865. The observations of this constellation form the latest as yet published volume of the "Annals," issued, in 1867, under the supervision of Prof. T. H. Safford, then director of Dearborn Observatory, but formerly in charge at Harvard as assistant in the observatory. For Mr. G. P. Bond's work, and especially for his observations on Donati's comet, he received a gold medal from the Royal Astronomical Society in 1865.[1]

Since the year 1866, in which the present director, Prof. Joseph Winlock, took charge of the observatory, its work has been yet further most successfully extended into new fields of research, by his own labours, and those of his able assistants, Messrs. Searle, Rogers, and Peirce. Besides what is known as routine work of all observatories, spectroscopic observations of the sun and of stars and nebulæ, and the most careful photographs of the sun, have been frequent. Five hundred drawings of the sun were made between January 1872 and November 1873, and 500 careful drawings of solar prominences in the year 1873. To this work is to be added a great deal of labour given to the determination of longitude differences, and the observations, by Prof. Winlock, of the solar eclipse of 1869, at Shelbyville, Kentucky, and that of 1870, at Jerez, in Spain. The general reader, as well as the astronomer, cannot fail to be interested in the beautiful pictorial representations of these and of other astronomical phenomena which have been issued by subscription recently from Harvard.

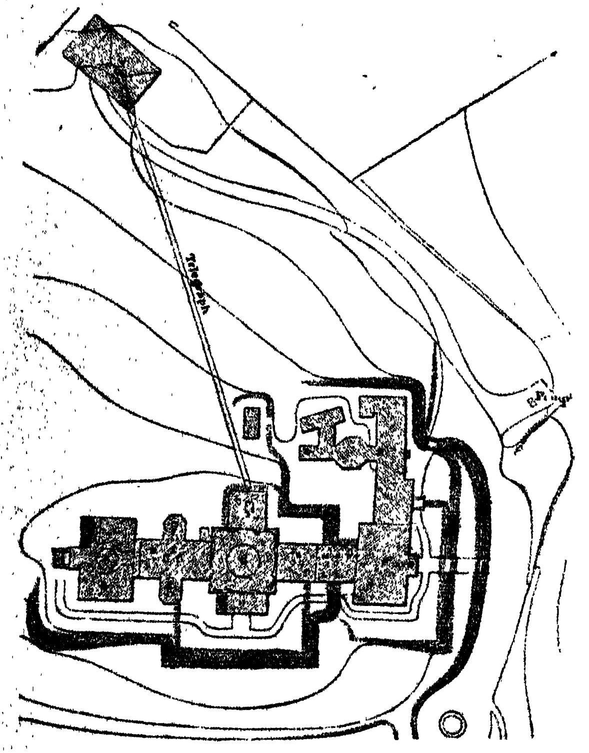

FIG. 3.—Ground plan of Cambridge Observatory. A, west equatorial; B, library; C, computing-room; D, west transit; E, new piers for new transit circle; F, collimator piers; G, east equatorial; H, grand entrance and stairs to east equatorial; I, prime vertical room and north clock; K, east transit; L, south clock; M, east clock; N, Chronograph; O, anemometer register; P, director's house; Q, front door; R, magnetic observatory; S, rain-gauge; T, anemometer.

The great equatorial, made in 1847 by Merz and Mähler, of Munich, has an object-glass of 15 in. in diameter, and a focal length of 22 ft. 6 in. The power of its eyepiece ranges from 100 to 2,000; the hour-circle is 18 in. in diameter. The movable portion of the well-balanced instrument is estimated at three tons. Its original cost was about $20,000. The sidereal motion given to this telescope is now secured by clockwork from Alvan Clark, which is spoken of by the observers as the only known "driving-clock working with perfect steadiness." The telescope rests on a central granite pier, in constructing which 500 tons of granite were used. It is 40 ft. high, and rests on a wide foundation of grouting 26 ft. below the ground surface. Upon the top of the pier is laid a circular cap-stone 10 ft. in diameter, on which is the granite block, 10 ft. high, bearing the metallic bed-plate. This instrument is in the central "Sears Tower."

The meridian circle was mounted in the west transit-room in 1870. It has modifications, introduced by Prof Winlock, not usually found in transit instruments, chiefly, that the graduated circles are directly above the piers, the bearings of the pivots being carried by iron standards; the axis friction rollers rest on rods rising from the base of the piers and counterpoised below the floor. The pivot circles and reading microscopes are protected by glass casing; the object-glasses of the transit and of each of its collimators, made by Clark, are each 8 in.

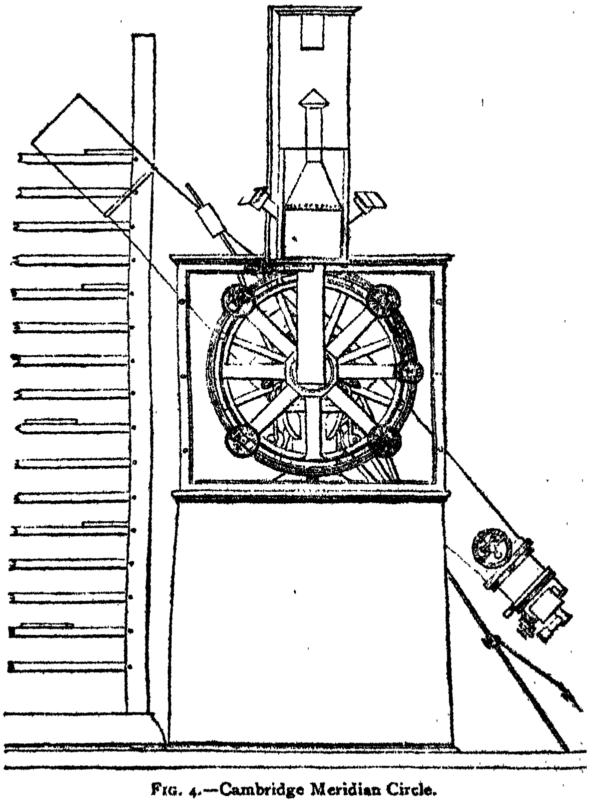

FIG. 4.—Cambridge Meridian Circle.

In the west dome is another Clark equatorial, made in 1870, with an object-glass of 5½ in. In the east wing is the transit circle made in Prof. Bond's directorship, by Simms, of London. Its focal length is 65 in., its object-glass 4⅛ in.; its circles are 4 ft. in diameter, read by eight microscopes to single seconds. Cambridge possesses a number of more modern instruments, constructed to meet the wants of astronomical investigations at this day.

The spectroscopes, photometers, and photographic apparatus are peculiar in form and power. The spectro scope used with the west equatorial in solar observations powerfully disperses the rays of light, which are carried twice through a train of prisms. In photographing the sun a lens of long focus is used, the light being thrown upon it by movable plane mirrors. This plan of Prof. Winlock's was adopted by the astronomers who went out under the U.S. Government to observe the Transit of Venus in December, 1875.

---

[1] Mr. Bond was the first American, we believe, to be thus honoured with the gold medal of a foreign scientific society. Prof. Watson, of Ann Arbor, and more recently Prof. Simon Newcomb, of the United States Naval Observatory, have been the recipients of like honours; the former from the Imperial Academy at Paris, the latter last year, from the Royal Astronomical Society of London.

The photometer, or light measurer, made by Zöllner, has been used for three years by Assistant Prof. C. S. Peirce. The design is the accurate measurement of the magnitudes of all stars in Argelander's Uranometria between 40° and 50° north declination, determining these magnitudes on a scale of uniform ratios of light, so that the probable error of one observation shall not exceed the tenth of a single magnitude. The great object of this is, that throughout Europe and the northern part of the United States there will be constantly enough of accurately determined stars near the zenith to serve as comparisons for any star visible to the naked eye whose magnitude is to be estimated. The secondary object is the prosecution of inquiries with regard to the distribution of the stars in space, their magnitudes and variability.

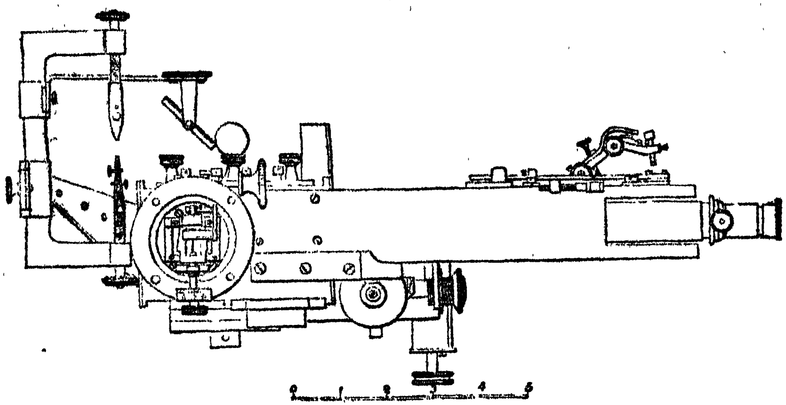

Fig. 5.—Cambridge Star Spectroscope.

The true time is daily given from this observatory to the State-house and other places in Boston, and by means of the telegraph lines to the whole of the New England States. It is received directly at noon each day without the intervention of any operator; the various lines being merely switched into the time line, the same click is heard at the same moment over the Eastern States.

Much more, however, than this is done for securing accuracy of time at any hour of the day. If anyone wishes to learn not only what the true time is, but whether his own watch is a good timekeeper, he may readily do so by a visit to the State-house in Boston. The arrangement for this, introduced by Prof. Winlock, is as follows:—The observatory clock is put in circuit at one end of a telegraph line, connected with which, at the State-house and other points, is an ordinary telegraph sounder. When the clock breaks the circuit by every second swing of the pendulum, a click of the armature of the sounder is heard at each of these points. The clock being so arranged that at every fifty-eighth second the break ceases, and at every even five minutes twelve breaks cease (no clicks being then heard), any person can, by listening to the sounder, compare his own watch with the standard clock. He can tell whether his watch is fast or slow by watching when the sounder ceases, the first click after the short pause being always the beginning of the minute, and the first click after the long pause the beginning of an even five minutes, as shown by the face of the clock in the distant observatory.

This standard motor clock is of course regulated with extreme care. It is customary, for the government of its rate of motion, to use shot of different sizes, which, according to the size, produce a change in the rate of the pendulum varying between 0·05 and 0·10 of a second per day. These are used as the astronomical correction for clock error may require. The time given by the standard clock thus regulated is that of the meridian near the State-house, sixteen seconds east of the observatory. Prof. Winlock considers that the use of the telegraph sounder gives a more satisfactory accuracy of time than can be given by other clocks which are put within the circuit and controlled, as is usual, by the standard clock; for in their case a variation in the strength of the electric current introduces an error in the beats of the pendulum, but the telegraph sounder must give the time with entire accuracy.

With so much before one at Cambridge of which interesting note could be made, one can do no more than attempt to trace its early and munificent endowment, its earliest discoveries under its first labourers, and the steady and recently very rapid advances not only in the highest objects of an observatory—exactness throughout extended series of observations—but in the exercise of professional skill in the invention and manufacture of the best appliances of the day for carrying on these investigations.

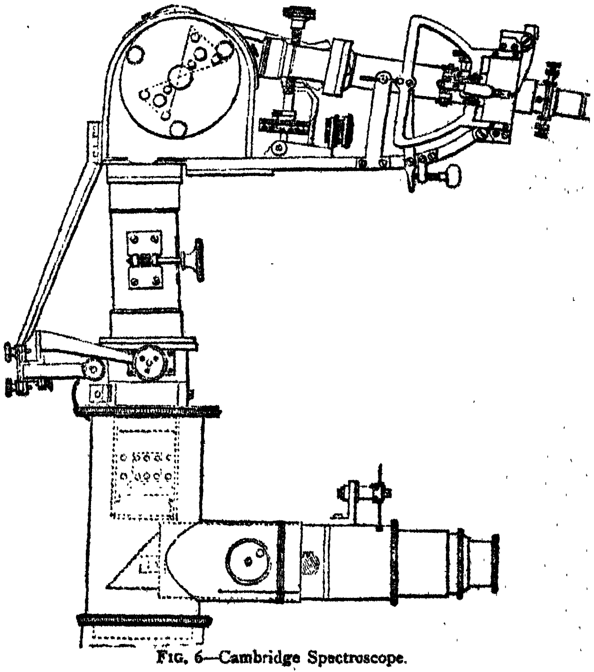

Fig. 6—Cambridge Spectroscope.

MUSEUM SPECIMENS FOR TEACHING PURPOSES[1]

III.

I NOW pass to the second great division of museum preparations, those that are preserved in a fluid medium; the only way in which the greater part of the structure of most animals, both vertebrate and invertebrate, can be kept from change and decomposition.

The first question for consideration is the best preservative medium. The one which has been most extensively used in all countries is alcohol. Various substitutes, as solutions of common salt, alum, bichloride of mercury, or arsenic, have been proposed and tried, chiefly on account of the expense of alcohol, and other slight disadvantages, but after a few trials these have generally been given up. At all events, the experience of alcohol in all the large museums of this country, has been so satisfactory compared to that of other media, that it is now alone used. The objection of expense which was caused by the high duty, has been in a great measure obviated by the permission to use "methylated" spirit, duty free, though some disadvantages have been thereby entailed.[2]

There seems little doubt but that a mixture of alcohol and water (commonly known as "spirits of wine," or when spoken of in relation to anatomical purposes, as "spirit" only) of the proper strength will preserve an animal substance for an indefinite length of time. There are specimens in the exhibition, (No. 3878 *a*), belonging to the Museum of Anatomy of the Academy of Science at St. Petersburg, prepared by the celebrated Dutch anatomist Ruysch, and bought from him by the Czar Peter the Great, in 1717, still in a perfect state of preservation. We have now in the Museum of the College of Surgeons many thousand preparations put up in the last century by John Hunter, and which appear to have undergone no changes beyond those which took place during the first few weeks of immersion in spirit, and which may be described as a certain amount of hardening and contraction of the tissues by coagulation of the albumen contained in them, and discharge of much of the natural colour.

The extent to which these changes take place depends very much upon the method with which the specimen is treated in the first instance. Sometimes it is desirable to harden the structure rapidly, as in preparations of hollow viscera, when the form alone is essential, in others, where preservation of the general appearance and the texture of the tissue is more requisite, and where further dissection is likely to be required, it is best to keep it as much as possible of the natural softness. The first condition is produced by immersing the preparation, when placed in the position in which it is to remain, in alcohol of the greatest strength, which afterwards may be diminished; the latter by beginning with a weak solution and gradually increasing the strength up to that finally used for permanent preservation.

The strength of the alcohol is estimated by its specific gravity, ascertained by the instrument called the hydrometer. But we do not speak of the actual specific gravity of physicists, but follow the conventional standard of the spirit-trade, the starting-point being taken at what is called "proof" at a temperature of 60° F., and the scale divided into degrees or "per-centages" above and below proof. By 1 per cent., or 1 degree under proof, is meant proof spirit with one-hundredth part (by bulk) of water. Spirit 10 per cent. under proof is a spirit consisting of 90 parts of proof spirit and 10 of water. On the other hand, by 10 per cent. over proof is meant that 100 parts (by bulk) of such spirit will require 10 parts of water to bring it to proof.

The "rectified spirit," as commonly sold, is about 60 or 65 per cent. above proof. This is only used for hardening preparations.

For ordinary use in the museum, proof spirit is strong enough, though to be quite on the safe side we generally use 10 per cent. over proof, diluting the rectified spirit with distilled water till it is reduced to the requisite strength, as ascertained by the hydrometer. This is the strength commonly used for all kinds of preparations, though it might be varied with advantage in some cases.

In estimating the preservative power of spirit, consideration should be given to the bulk of the specimen, and especially the amount of water contained in its tissues, as compared with the quantity of spirit used. For instance, if a large solid mass of animal substance is placed in a jar little larger than sufficient to contain it, filled up with proof spirit, the amount of fluid contained in the specimen will so dilute the spirit that decomposition, especially of the interior of the specimen, to which the spirit cannot penetrate, will not be prevented, whereas a smaller specimen placed in the same jar of spirit will be preserved perfectly. Many collectors of objects of natural history do not attend sufficiently to these considerations, and hence the specimens become spoiled, much to their disappointment or to that of their consignees. The way to obviate this is not to use stronger spirit, as that would harden the exterior of the specimen, and prevent the spirit penetrating to the centre, but to use greater bulk of spirit, and especially to change it, after a day or two, pouring away the old diluted spirit, and substituting fresh, repeating the process if necessary more than once.

When a specimen has once been thoroughly saturated with spirit, and its tissues hardened, a strength much below proof will be sufficient to preserve it. The nature of the specimen must also be taken into consideration. For instance, nerve tissue, as in the brains of animals, requires stronger spirit for its preservation than ligamentous or fibrous tissues. Much will also depend upon the freshness of the specimen. If decomposition has already set in before it is placed in spirit, it will require much stronger spirit, and more frequent renewals than if it is fresh.

With most preparations it is desirable to cleanse them well before mounting them in spirit. They should be left a few hours or days (according to the temperature) in water frequently renewed, and the blood should be washed out of the large vessels, by means of a stream of water directed through them. This will save to a large extent the discoloration of the spirit into which they are placed. When removed from the water they should be allowed to drain, and be gently dried with a cloth before placing in the spirit, but no part of them must on any account, at any time during the process of preparation, be allowed to become actually *dry*, otherwise dark stains which are quite irremovable will be produced. This precaution is most essential when they have been once in spirit, and are removed for examination or further dissection, as evaporation of the alcohol, and consequent desiccation of the preparation, takes place much more rapidly than that of water.

In most cases it will be requisite to change the spirit once or oftener, before all the soluble colouring matter is given off from the preparation, and it can be permanently mounted. The discoloured spirit need not be wasted, as it can be perfectly restored by passing through the still.

To succeed in making a good anatomical preparation, much patience, neatness of hand, knowledge of the subject illustrated, and some artistic talent are required. No pains should be spared to make it tell the lesson it is intended to convey in the most attractive and pleasing manner. Everything should be displayed as definitely and clearly as in a drawing, and there should be no appearance of negligence or want of finish in any part.

When an elaborate dissection is required, it must, at least in all its later stages, be carried on while the specimen is under spirit, fixed in a flat dish or basin. The small fragments of connective tissue which have to be removed then float out from between the fibres of the muscles and the vessels which are to be preserved and exhibited, and they are carefully snipped off with fine curved scissors. A dissection which looks clean and highly finished as long as it is in air, when placed in fluid, becomes at once cloudy and obscure, from the floating up of these little particles. Hollow viscera, as hearts or stomachs, are distended by injecting their interior with strong spirit, tying or plugging the apertures by which it could escape, and placing them for several days in a vessel with the same fluid. If all the requisite precautions are taken, they will then preserve their form, and the interior of their cavities can be exhibited, by cutting openings or "windows" through different parts of their walls. If from any cause a cavity cannot be made to contain spirit, it may be stuffed with cotton-wool or horse-hair during hardening. The preparation, when laid aside to harden, if not suspended, should be placed in a bed of cotton wool adapted to its form, otherwise it will become irremediably flattened on the side on which it rests.

---

[1] Lecture at the Loan Collection of Scientific Apparatus, South Kensington, July 26, 1876, by Prof. W. H. Flower, F.R.S., Conservator of the Museum of the Royal College of Surgeons of England. Continued from p. 186.

[2] Methylated spirit is decidedly inferior in transparency and in absence of colour to pure spirit, and even if bright when first used, is apt to become turbid after a time. In a large establishment this can be to a great extent remedied by passing the discoloured spirit through a still, but it would be very desirable to consider whether some other method could not be devised by which alcohol could be used for scientific purposes, without the necessity of paying the present heavy duty of sixteen shillings and sixpence a gallon.

Preparations are usually mounted in glass jars, open at the top, and with a foot below, and either circular or oval, *i.e.* flattened on two opposed sides. The form is selected according to that of the preparation. The ovals show off some preparations to greater advantage than round bottles, but have the disadvantage of being more expensive and being (especially when of large size) liable to crack spontaneously, and apparently without provocation, but probably in consequence of some alteration of temperature affecting the unequal tension of the outer and inner surface of the glass at the bent ends.[1]

The fine silk threads by which the preparation is to be suspended are brought over the edges of the jar, and passed beneath an ordinary thread tied round the groove, then returned and secured across the top of the jar. As threads fastened in this way occasionally are the means of causing leakage of the spirit, with which of course they are always saturated, some prefer to tie them to a piece of wood, or whalebone, fixed across the mouth of the jar. The only disadvantage of this is that it entails some additional trouble, and a reduction of the number of points of suspension which may be made use of in the other method.

There are two methods generally adopted for closing the upper end of the jars after the preparation is mounted in it. The oldest, and still very generally used, is by means of successive layers of bladder, tin foil, thin sheet lead, bladder again, and finally black varnish. The bladder must be macerated until it is partially decomposed, and then it will adhere firmly to the glass. This necessity makes the process a disagreeable and dirty one. The object of the tin foil is to protect the lead from the oxidisation which always takes place when the vapour of spirit comes in contact with it through the first layer of bladder, tin not being so acted upon. A layer of tin only would answer as well as the tin and lead, but if thick enough for the requisite strength, would be more expensive and less easily worked round the edges of the glass. The thin sheet of tin is gummed to the surface of the lead, and then they are cut together to the requisite size, and treated as one, the tin being of course placed downwards. The edges are firmly pressed down round the lip at the top of the bottle and into the groove, with pieces of box-wood shaped for the purpose. Much of the success in closing the bottle depends upon the care with which this is done. Then the second layer of bladder is put on, and tied firmly with twine, round the groove at the top of the bottle. When thoroughly dry the twine is removed, and the edges of the bladder neatly trimmed with a knife; it is afterwards coated with one or two layers of black paint and a layer of black japan varnish.

Bottles closed in this way often keep in the spirit for many years without any material alteration in its level, but there is generally a slight evaporation, so that they have to be watched, and whenever the spirit gets so low that the safety of the preparation is endangered, the old cover must be cut off, and the specimen remounted and closed in by the same process.

A more expeditious and cleaner process, which has also the advantage of admitting light to the top of the preparation and allowing it to be seen from above, is by the use of glass covers. The top of the bottle is ground smooth, and a cover of glass of thickness suited to the size of the bottle cut to fit it. Many practical difficulties have been encountered in carrying out this process, but they have been mostly surmounted by experiment and perseverance, and it probably will in time entirely supersede the bladder and lead plan.

One cause of difficulty was the frequent breakage of bottles so fastened; upon changes of temperature; in the other plan, the top, being somewhat flexible, yields with the varying state of expansion of the contents of the jar, but the glass top is perfectly rigid, and if the pressure is too great must either separate from the bottle or break. This occurs chiefly in large bottles where the bulk of spirit is great, and consequently its expansive power out of proportion to the strength of the glass. This can be obviated to a great extent by not filling the bottle completely, as then the layer of air at the top, being far more compressible than the spirit, acts as a sort of buffer between the bottle and the glass; but in large bottles we generally take the further precaution of a small safety-valve; a hole drilled through the cover, with a loosely fitting stopper to check too great evaporation, or the ingress of dirt. Through this hole the jar can be filled up with spirit, when required, without the necessity of disturbing the preparation, as in the old process.

A second difficulty with glass-covered jars was to find a cement to fix the top, at the same time easy of application and not dissolved or weakened by the spirit. Isinglass dissolved in strong acetic acid, pure gutta percha, a mixture of pitch and gutta percha, and other substances, have been successively used in the Museum of the College of Surgeons, but finally we have given them all up for a composition sold as "Rock marine glue."[1] It is applied in a melted state, the edges of the glass cover being also heated. A small gas jet fixed on a flexible tube greatly facilitates this process.

The suspending threads can either be fixed to a glass rod placed across the top of the bottle just below the glass cover, the ends of which are let into notches cut for the purpose on opposite sides of the inside of the upper rim of the jar, or they can be brought out between the top of the jar and the glass cover, embedded in the cement, and secured by a string tied round the top of the bottle till the cement is hard, when they can be cut off close to the outer edge of the cover, and the securing string removed. The preparation is then finished by neatly painting the edge of the covering glass and cement, and the neck of the bottle for a short distance below, with two or three coats of black varnish.

For displaying different parts of the preparation, especially canals or cavities, black and white hogs' bristles and variously coloured glass rods are used. Delicate preparations, which cannot be kept in position if simply suspended, are fastened by stitches to thin transparent plates of mica, or to opaque coloured slabs of wax, or cardboard. Black or blue are the colours generally preferred, as in greatest contrast to the usual colour of preparations, as shown in the beautiful series of dissections illustrating the anatomy of the frog (3,904 *c*) contributed by Prof. Huxley.

I have said nothing yet about injecting preparations, a process necessary in order to display the course and distribution of blood-vessels. There are two kinds of injections, fine and coarse; the former fills the capillary vessels, and for preparations intended to be seen with the naked eye, gives a blush of the colour used to the tissue, and is chiefly valuable as indicating the relative amount of vascularity of contiguous tissues. For microscopical investigations it is invaluable, and the methods employed and the materials used are fully detailed in all works devoted to microscopical manipulation. Coarse injection is intended only to show the vessels visible to the eye, and not to enter into the capillaries. Size, so generally used as a basis for fine injections, is not so satisfactory in this case, as if in any bulk it contracts in the spirit. The best material (introduced by Dr. J. B. Pettigrew, F.R.S., when Assistant in the Museum of the College of Surgeons) is fine plaster of Paris, coloured with vermilion or ultramarine, according as the tint of red or blue is required. It is mixed with water, as in taking casts, though of rather a more fluid consistence, and of course must be injected immediately, or it will set in the syringe. It has the great advantage of being used cold. It is rather brittle when set, and the vessels should be handled with care, but it may be made more tenacious by the addition of some glue or isinglass to the water with which the plaster is mixed.

The distinction between two different kinds of tissue is sometimes well shown by staining the preparation. Some good examples are exhibited by the Anatomical Museum of the University of Oxford. The head of a sturgeon (Nos. 3,837 and 3,838, prepared by Mr. Robertson) has been immersed for a short time in a solution of carmine, and the cartilage and connective tissue has received the colour, while the bones retain their natural white hue. The distinction between them, which otherwise would scarcely be perceptible in the bottle, is thus very clearly brought out.

The third and last great division of museum specimens for teaching purposes, illustrated by this exhibition, is that which comprises models and casts of natural objects, and under the same heading drawings and diagrams may be included.

As a general rule, models should never be used for teaching if actual specimens can be obtained and exhibited; but there are numerous cases in which the object is of so perishable a nature, that it cannot be preserved efficiently by any of the methods above described. Many objects are so scarce that it is quite out of the power of most museums to possess any representations of them, except as copies of the originals.

---

[1] The greatest desideratum in putting up wet preparations is a durable glass jar with flat sides, so that the distortion of the object caused by the refraction through the curved surface of the glass may be avoided. Built up cells do very well for small objects, but they are very expensive, and generally fail when tried on a large scale. The subject still offers a good field for experiment.

[1] It is bought from Rockhill and Co., 10, Blackfriars Road.

There are also others so small, that for lectures and demonstrations an enlarged model is of very great assistance.

What may be done in teaching natural history by means of models and coloured casts is admirably shown in Mr. Frank Buckland's museum in this building, where may be seen accurate representation of many of the species of Cetacea and larger fish of our seas, giving a more complete idea of their size, form, and colour, than has ever been produced by any other method. The reduced models of animals and men of various races exhibited by the Committee of the Pedagogical Museum of Russia are also interesting, and must be useful aids to school teaching. By what other means, for instance, could the singular form of such an animal as the Greenland right-whale be brought before a class of pupils? I would also call attention to the well-known anatomical models of Dr. Auzoux, of Paris (which by the way are not very fully represented in the present exhibition by Nos. 3,829 *a* to *d*); to the models illustrating the development of the trout, by Dr. A. Ziegler, of Freiburg (No. 3,839); to the enlarged models of blood corpuscles of different animals for illustrating their form and size, by Prof. H. Wolcker, of Halle (No. 3,893); to the models of Radiolaria in *papier mâché*, by V. Fric, of Prague (No. 3,865); to the numerous anatomical models of Strembitsky in the Russian collection, of Rammé and Todtmann, of Hamburg (Nos. 3,868–3,877); and of Tramond, of Paris (Nos. 3,923–3,925); to the casts of different parts of the human body dissected, by Steger and Honikel, of Leipzig (Nos. 3,840–3,842); and to the models by various exhibitors illustrating the structure of flowers and seeds.

With reference to such models, the importance of accuracy of execution cannot be too strongly insisted upon. With a cast of course there is not much chance of error, but for the accuracy of a model, especially when on a different scale from the original, we are entirely dependent upon the artist's skill and care. The only fault to be found with most of those in the exhibition is that they are rather too rough in execution to be pleasing to the eye, but it has been in most cases an object to produce them at such a low price, as would not be compatible with fine workmanship.

Although I have only been able in the time allotted to glance briefly at the various branches of the subject which I have been requested to expound, I trust that some suggestions have been given in this lecture which will be found of use to those who have the care of collections, and that I have succeeded in showing that the art of preparing, preserving, and displaying specimens in museums is one which deserves to be more fully cultivated than it has hitherto, as a most important adjunct to the diffusion of biological knowledge.

OUR ASTRONOMICAL COLUMN

THE NEW STAR IN CYGNUS.—Prof. Schmidt has published details of his observations of this star from November 24, the date of discovery, to December 15, and has also put upon record the dates, between November 1 and 20, when he had examined the constellation Cygnus, with the view to show that a star as bright as the fifth magnitude could not have escaped his notice, and therefore that the rise of the new one to the third magnitude must have been very rapid, as also appears to have been the case with T Coronæ in 1866. On the evening of its discovery the star was strong golden yellow, and writing on December 9, Herr Schmidt states it had always been of a deep yellow, but at no time exhibited the redness of its neighbour, 75 Cygni. The following are the magnitudes on different nights as determined at Athens by careful comparisons with ρ, π^2, τ, ζ and ϕ Cygni, and η Pegasi :—

	m.		m.		m.	
Nov. 24	3·0	Dec. 2	5·4	Dec. 11	6·7	
25	3·1	3	5·6	12	6·7	
26	3·1	4	5·8	13	6·8	
27	3·2	5	5·9	14	6·9	Hardly visible to naked eye.
28	3·8	7	6·3			
29	4·7	8	6·5	15	7·0	Visible so, for last time.
30	5·0	9	6·6			
Dec. 1	5·2	10	6·5			

On the evening of December 31 the new star was about 7m. and very decidedly orange. It has but slowly diminished during the last three weeks.

NEW VARIABLE STAR IN CETUS.—Mr. J. E. Gore, writing from Umballa, Punjab, on November 28, draws attention to a star entered on Harding's atlas as a sixth magnitude, about 1¼° distant from 59 υ Ceti, and 13′ *s.p.* Lalande 3590. On November 18, this star was only 8m., considerably fainter than a 7m. star shown by Harding, closely preceding υ.

This star is not in any of the catalogues, nor in Schjellerup's list in No. viii. of the publications of the *Astronomische Gesellschaft*. Reading off from Harding and reducing to 1877·0 its position is in R.A. 1h. 50m. 13s., N.P.D. 110° 59′.

DE VICO'S COMET OF SHORT PERIOD.—It was remarked in this column last week, that unless the orbit of De Vico's comet of 1844 has undergone some violent perturbation, a perihelion passage may be expected to occur during the year just commenced. It appears, however, that the chances of detecting the comet, should it arrive at its least distance from the sun during the first three months of the year are very small indeed, and hence, unfortunately if the comet is not found between July and December, it cannot be inferred with any degree of certainty that it has not passed its perihelion within the twelvemonth. The following places are calculated from Prof. Brünnow's last orbit for 1844, reduced to the equinox of 1872, supposing the arrival at perihelion to fall either on the date mentioned or thirty days before or after it. Δ is the comet's distance from the earth.

Time from Perihelion.	January 1·0.			February 1·0.		
	R.A.	Dec.	Δ	R.A.	Decl.	Δ
− 30 days	302°·1	− 21°·8	2·13	316°·4	− 18°·3	2·23
0 „	317·9	− 18·1	1·85	331·6	− 13·4	2·10

THE TOTAL SOLAR ECLIPSE OF STIKLASTAD, 1030, AUGUST 31.—The circumstances under which this eclipse occurred are given by Prof. Hansteen, of Christiania, in *Ergänzungs-Heft zu den Astronomische Nachrichten*, p. 42, with elements computed from the tables of Burckhardt and Carlini. Sir George Airy has also published elements of the eclipse, resulting from Hansen's calculations from his Solar and Lunar Tables, as an addendum to the paper on the eclipses of Agathocles, &c., in vol. 26 of the Royal Astronomical Society's *Memoirs*, having previously drawn attention to the circumstance that the eclipse of Stiklastad, from the narrowness of the belt of totality and its having been total at a well-defined point, might, in combination with the eclipse at Larissa, B.C. 557, May 19, be of much value in throwing light upon corrections possibly required for the lunar tables.

The following elements of this eclipse are founded upon the same system of calculation for the moon's places, to which we lately referred as having been applied to the Nineveh eclipse of B.C. 763, with the sun's place from Sir George Airy's paper :—

G.M.T. of conjunction in R.A., 1030, Aug. 31, at 1h. 20m. 40s.

	°	′	″
R.A.	164	20	54·1
Moon's hourly motion in R.A. ...		33	14·8
Sun's „ „ „ ...		2	15·3
Moon's declination	7	37	23·3 N.
Sun's „	6	43	1·6 N.
Moon's hourly motion in decl. ...		10	20·8 S.
Sun's „ „ „ ...		0	56·0 S.
Moon's horizontal parallax		58	18·1
Sun's „ „			9·0
Moon's true semi-diameter		15	53·2
Sun's „ „		15	56·5

Points on the central line would fall in long. 10° 22′ E., lat. 64° 6′ N., and in long. 14° 31′ E., lat. 61° 41′ N. Hansteen gives for the position of Stiklastad 11° 35′ E., and 63° 48′ N., which by the above elements would be only 10′ outside the northern limit of totality. On making a direct calculation for the longitude of Stiklastad, we find that the duration of totality could not have exceeded twenty seconds on the central line.

METEORS OF DECEMBER 11.—MM. Perrotin and Jean, at the Observatory of Toulouse, observed a considerable number of meteors on the night of December 11; between 11h. and 13h. 106 were counted, the majority of which, according to M. Perrotin, radiated from a point in about R.A. 115°, N.P.D. 57°, near Castor and Pollux, though closer to the former star than to the latter. The trajectories were very short, so that it was difficult to refer them to a chart. The sky was overcast on the following night.

NOTES

WITH reference to the closing of the Loan Collection, a circular has been issued by the Lords of the Committee of Council on Education, stating that, although in consequence of the funds at their disposal for the Collection being exhausted, they have found it necessary to close the Exhibition, arrangements are being made for the safe custody of all objects which may be left on loan to the Museum, pending the decision by Her Majesty's Government on the offer made by the Royal Commissioners for the Exhibition of 1851, of a building for the establishment of a permanent Science Museum. The Lords of the Committee of Council on Education also inquire whether exhibitors are willing to leave the objects contributed till this question be settled. The closing of the Exhibition will not interfere with the delivery of the Free Saturday Evening Lectures.

ACCORDING to the will of Dr. C. A. Bressa, dated September 4, 1845, the testator left all his property to the Royal Academy of Sciences of Turin, the net interest to be given every two years as a prize for the most important discovery made or work published during the previous four years on natural and experimental philosophy, natural history, mathematics, chemistry, physiology, and pathology, as well as geology, history, geography, and statistics. This is to be given alternately to a person of any nation and to an Italian. Signora C. A. Dupêché had a life interest in the property, and it was not until July last that the legacy became free from all claims, and the first prize will be given in 1879, open to all, and of the value of 480*l.* In accordance with the spirit of Dr. Bressa's will, the Academy will choose the best work or discovery, whether or not it be presented by the author.

WE are informed that the valuable collection of fossils from the Red Crag made by the Rev. H. Cahnam, of Waldringfield, including, among the most important, the remains of *Halitherium* described by Prof. W. H. Flower, teeth of *Mastodon*, &c., has been purchased by Sir Richard Wallace, and most liberally presented by him to the Ipswich Museum.

THE Dutch Society of Sciences at Haarlem has offered a gold medal for the best answer to the following question:—What are the meteorological and magnetical periodic changes which may be considered to be in a well-established relation with the period of the solar spots? The answers must have a motto and be accompanied with a sealed letter containing the name of the author. They should be sent before January 1, 1878, to the Secretary, Prof. von Baumhauer, Haarlem.

RUSSIAN newspapers announce that the Helsingfors professor, Dr. Ahlquist, a well-known explorer among the tribes of Northwestern Siberia, will start, next spring, for further ethnological explorations among the Voguls and Ostyacks of the Obi and Irtysh. He will be accompanied by two assistants, the Senate of Finland having allowed a sum for the travelling expenses of the explorers.

AT a recent meeting of the Manchester Literary and Philosophical Society a letter was read from Mr. Joseph Sidebotham in which he calls attention to the fact of the growing use of the aniline colours for tinting photographs. He finds they are being *extensively* used in paintings and water-colour drawings, and the colours regularly sold for that purpose. Anyone who knows the speedy alteration by light of nearly all of these colours will protest against their use, and a statement of this with the authority of some of our chemists would probably have the effect of causing them to be discontinued by all artists who care to think that their works should last more than a single year.

ON the night of the Arlesey railway accident there were six Indian elephants on their way by train from Huddersfield to London. Two were large and the others quite young. The tarpaulin over the trucks in which they travelled was blown away in the gale, and the animals were thus exposed to the snow and sleet and cold wind of that night. They were also delayed long on the road in consequence of the accident. One of our contributors who saw them "unloaded" at King's Cross, and noticed that they walked very stiffly at first, has inquired of Mr. Harrington, their keeper, whether the cold journey has affected them. He has written in reply that they seem perfectly well, and he cannot see that the unusual exposure has had any effect on them. None of the animals have been more than a few years in England. As Mr. Harrington's letter is written nine days after the journey, no effects of chill are likely now to show themselves. The Indian (and perhaps the African) elephant may be better able to withstand sudden climatical changes than is generally supposed.

OUR Samoan Correspondent, the Rev. S. J. Whitmee, announces the publication of a new Dictionary of the Samoan language by himself and the Rev. G. Pratt. Mr. Whitmee is on his way to England, where he will probably arrive in spring. Intending subscribers—and we hope there will be a considerable number in this country—should address Mr. Whitmee at the Mission House, Blomfield Street, Finsbury, E.C. The price, it is hoped, will not exceed 10*s.*

WE have received reprints of the letters which M. Poliakoff has written during his recent journey for the zoological exploration of the Obi and Irtysh. They contain many valuable observations on the physical characters of the country visited, on its fauna, on the migrations of fishes up and down the Obi, and on the fisheries, on the migrations of birds, together with a variety of interesting occasional observations. We may hope therefore that the report on this journey will be a valuable addition to the zoo-geography of Western Siberia.

M. POLIAKOFF gives the following particulars confirming the law of Baer as to the deviation to the right of rivers running north and south. The bed of the Irtysh being cut in loose deposits, these deposits are constantly undermined by water on the right bank. Each spring a strip of the bank from 30 to 50 feet broad is destroyed by the waters. Sometimes it happens that a strip from 70 to 140 feet broad and about 150 yards long falls suddenly into the river. The course is then barred for a short time, and a great wave propagated up and down the stream, destroys the fishing-boats which happen to be at work within a distance of about ten miles from the spot. Large quantities of fishes are also found, after such a catastrophe, on the shores, suffocated in the muddy waters. The destruction of the right bank going on constantly, year after year, the villages are also constantly advancing to the east; one of them, Demiansk, has thus travelled about a mile in the course of 240 years. The left shore shows, therefore, a low tract of land covered with ponds and marshes, and yearly overflown, whilst the right shore faces the water with abrupt crags from 70 to 150 feet high. The same thing is also observed on the Obi. The hills of Bélogorie, a short way below the mouth of the Irtysh, have now the main bed of the river to their right, while some time ago it was on their left, there being now on the latter side only a secondary arm. These arms of the Obi—remains of its former beds—form on the left flat shore a series of elongated ponds and channels, connected with the main body of the river by a labyrinth of smaller water-courses.

IN the article in last week's number on Dr. Schliemann's Discoveries, *Amyclæ* was misspelt *Amychi*, Sir R. Colt Hoare's name was given as *Home*: *Arena* should be *Arma* Heroum, *Micomedia* should be *Nicomedia*, and *Caprea*, *Capreæ*.

THE first number of a new quarterly scientific journal, devoted to zoology, botany, geology, and mineralogy, will be published at Buda-Pest this month. It will be in German, though its first title is "Természetrajzi Füzelek" ("Naturhistorische Hefte"). Prof. Otto Herman is the principal editor.

THE death is announced of the Rev. Barnard Smith, the author of many well-known educational works in arithmetic and algebra.

A WELL-DESERVED pension of 50*l*. a-year has been bestowed upon Mr. Thomas Edwards, the "Scottish Naturalist," whose life Mr. Smiles has written.

DR. PETERMANN has been informed that the Portuguese Government has granted a subsidy of 20,000*l*. in aid of the proposed great scientific expedition for the exploration of Central Africa. The expedition is already organised and will start without delay, commencing its operations by proceeding up the Congo.

THE *New York Herald* of December 2 and 11, contains letters on our Arctic Expedition, by Dr. Hayes.

IN the last report of the Berlin *Akademie der Wissenschaften*, J. Bernstein describes an exceedingly simple and ingenious apparatus for determining the position of the nodal point of the eye of a living person. Experiments with his right eye gave 7·21–7·38 mm. as the distance of the rear nodal point from the vertex of the cornea.

THE Royal Museum at Berlin has received a valuable donation of about 8,000 ethnographical objects from Dr. Jagor. They are the results of extensive journeys through East Turkestan, Burmah, and portions of India, and afford a most complete picture of the domestic and military life of the widely diversified tribes inhabiting the less known parts of these countries.

THE gorilla in the Berlin Aquarium which excited so much interest among German naturalists, has lately recovered from a serious illness, and is now more than ever demonstrative and humanlike in his movements. With the approach of winter a soft silky fur has made its appearance. The weight of this young gorilla has increased from thirty-three to forty-three pounds during his six months' residence in Europe, a fact which would seem to show that confinement is, after all, not so unendurable for him as was supposed.

A SERIES of new rooms has been opened at the *Musée d'Artillerie* of Paris, in which a set of guns is arranged showing the various models used since the artillery was introduced for the first time in warfare 600 years ago.

THE *Annuaire du Bureau des Longitudes* is publishing for the first time two interesting tables;—first, the situation of the several radiant points of falling stars, second, the catalogue of all variable stars, with a calendar of their variations during the year 1877.

MR. M'LACHLAN gives a few details in the *Entomologist's Monthly Magazine* concerning Capt. Feilden's collection of the insects of the Arctic expedition, which he has seen. The greater number of the insects were collected near Discovery Bay in 81° 42′ N. latitude; some of the *Lepidoptera* are even from 82° 45′. The most interesting fact is the occurrence of five or six species of butterflies within a few hundred miles of the North Pole, especially when taken into consideration with the fact that Iceland and the large islands of the Spitzbergen group, although in lower latitudes, have apparently no butterflies. In *Lepidoptera* Mr. M'Lachlan observed four examples (2 ♂, 2 ♀) of the genus *Colias*, possibly two species (? *Boothii* and *Hecla*). Apparently three species of *Argynnis* or *Melitæa* (or both). A *Chrysophanus* apparently identical with *phlœas*. In the *Noctuidæ*, only one individual—an *Acronycta*. In the *Geometridæ*, one *Amphidasis* or *Biston*, and several Cheimatobioid forms with apterous females. Of the *Crambites*, one *Phycis*, perhaps our *fusca*. The *Hymenoptera* are represented by a *Bombus*, and one of the *Ichneumonidæ* of considerable size. In the *Diptera* there is one large fly, probably belonging to the *Tachinidæ*, and perhaps parasitic on the larvæ of some of the *Lepidoptera*. One species of *Tipulidæ*; and a considerable number of *Culicidæ*, and of what looks like a *Simulium*, which, however, do not appear to have annoyed the members of the expedition in these high latitudes. Of *Coleoptera*, *Hemiptera*, and *Neuroptera*, Mr. M'Lachlan saw none; but the bird-lice are naturally well represented.

THE second International Congress of Americanists, organised for the Study of American Antiquities, will be held at Luxembourg on September 10-13, when all English students and *savans* will be cordially welcomed. Information and tickets may be obtained from Mr. Francis A. Allen, 15, Fitzwilliam Road, Clapham, S.W., one of the delegates for England.

THE December session of the *Deutsche Geologische Gesellschaft* was devoted to a long address from Herr Lohsen upon the Rammelsberg, in the neighbourhood of Goslar. The peculiar deposits of ore in this mountain he regarded as belonging to a much later epoch than that in which the surrounding slate was formed, while he explained the lens-shaped form of the cavities in which the deposits are formed as due to the enormous pressure of the overlying strata of sandstone.

THE recent death of Mr. James Drummond, of Comrie, deprives us of a local geologist. He had devoted much time and attention to the Comrie earthquakes, on which he had published many articles and a little book. His views were generally in disaccord with those of the observers appointed by the British Association, against whom he held out manfully.

THE large number of fossil plants brought home from Greenland and Spitzbergen by the two Swedish expeditions of 1870 and 1872 have been carefully examined by Dr. Oswald Heer, and they appear to throw important light on the geological development of the plant world. An account of his study of the remains from the chalk period appears in a recent number of the *Naturforscher*, and in the summary of his results Dr. Heer points out that the facts are against a gradual imperceptible transformation of plant types; from the upper chalk the dicotyledons appear suddenly in great variety, without any transition, whereas other forms at this period wholly disappear from the scene. Further, these researches make it very probable that a whole series of genera have had their origin in the Arctic zone, and have thence "radiated" southwards. Lastly, Dr. Heer shows that the facts at present known of plant palæontology do not point to any alternation of climate or repeated ice-periods in these regions (a view which has also been developed by Prof. Nordenskjöld).

DR. LAUDER LINDSAY has sent us a well drawn up programme of a subject for essays, to be substituted for the ordinary subjects set in schools. The subject is the Moral Education of the Lower Animals, and is intended to train the observing powers of the young, as well also to discover how far animals are capable of moral training.

AT a recent meeting of the Belgian Academy, M. Dupont announced the discovery of numerous vestiges of the age of polished stone in the neighbourhoods of Hastière-sur-Meuse. No less than fifteen burial caverns were discovered in the locality. Five of them have already yielded about fifty-five human skeletons and thirty-five sufficiently well-preserved skulls. Sixteen dwelling-places of the people who inhabited at that period the plateaux, are already explored, and have produced numerous flint weapons. These discoveries promise to throw much light on the pre-historic ethnography of the country.

THE Pennsylvanian Company, which was formed some time ago in order to convey the petroleum obtained in Pennsylvania from the wells to the seaports on the Atlantic, now intends to construct a tube of 4 in. diameter and of some 300 miles in length, connecting the wells with the sea. The practical possibility of the plan is proved by works, which, for a distance of 250 miles, are already in action and use. Baltimore was the first city with which these new canals were connected. The oil is forced through the pipes at a pressure of 900 lbs. on the square inch, and at intervals of fifteen miles large steam pumps, of 10-horse power, assist the motion of the stream. At Baltimore the canal ends in enormous tanks, and these are in direct communication with the refining works. The cost of the new canal and accessories is calculated at 1,250,000 dollars.

IN a note in the *Bulletin* of the Belgian Academy (vol. xlii., Nos. 9 and 10) Dr. Putzeys gives the results of his experiments on new anæsthetics belonging to the alcoholic series, viz., the bromides of ethyl, propyl, and amyl. Inhaled by frogs, rabbits, cats, and dogs, they were proved to possess the same properties as chloroform. The interest of the result is increased by the circumstance that many compounds of bromine from the fat series do not possess the same anæsthetic properties as the corresponding compounds of chlorine.

THE July number of the *Isvestia* of the Russian Geographical Society gives an interesting report by Col. Bolsheff on that part of the Pacific shores of Russian Mantchuria which lies between the 45° and 52° north lat., a country the interior of which remained very little known until now. Almost the whole of the land is covered with mountains, outliers of the Sikhotaalin, a ridge reaching in its highest point 5,173 feet, and abruptly falling to the sea with hills about 800 feet high. The high valleys, which sometimes have a breadth of seven miles, seem to be well suited for agricultural settlements. In the northern parts of the country, lead, silver, iron, copper, and gold, were discovered, this last seeming to occur in considerable abundance. The population is very thin, numbering but 550 souls, Chinese and Tazes, who carry on agriculture, and Gilyaks and Tunguses, living miserably by hunting and fishing. The settled Chinese and Tazes are also engaged in the collection of sea-weeds and sea-worms purchased in China, the Tazes being almost reduced to slavery by the Chinese. Various collections, especially botanical and entomological ones, were brought in by M. Bolsheff, and will be deposited at the Russian Geographical Society.

M. LIPPICH, of the Vienna Academy, has recently been investigating the influence of the mean distance of absorbent particles upon absorption. As such an influence must be especially prominent when the substances afford well-defined absorption bands, and, with considerable density, show no strong colours, he chose for his experiments the nitrate of didymium oxide, which has these properties in high degree. A pretty concentrated aqueous solution of this salt in a vessel 1 cm. thick was spectroscopically compared with a solution having concentration only 0·1, 0·05 . . . of the first. The solutions were in tubes of 10, 20 cm. . . . length severally. A Steinheil spectroscope was used, and the light sources were two gas lamps so regulated that both spectra showed the same brightness on the parts that were free from absorption. Even with the concentration-ratio 1 : 10, there were marked differences in the absorption bands. The very characteristic bands in yellow and yellow-green were, for the more concentrated solution, considerably broadened towards the red end of the spectrum, while the sharp limit towards the violet was the same for both solutions. The much narrower bands in the green showed quite a similar behaviour. In the other parts differences were observed with difficulty. Besides this difference in the breadth of the absorption bands, there were others in the distribution of the bright parts.

PROF. BERNARDIN, the indefatigable *conservateur* of the Commercial and Industrial Museum at Melle, near Ghent, has just published another of his useful lists under the title of *Classification de* 250 of *Fécules*. The arrangement is on a scientific system, the plants being classed under their natural orders, commencing with the Cryptogams and proceeding with the higher developed plants. The scientific name of the plant is placed first under each order and is in italics so as easily to catch the eye. The lists previously compiled by Prof. Bernardin are *Classification des Huiles Végétales*, *Nomenclature de* 550 *Fibres Textiles*, *Classification de* 250 *Matières Tannantes*, *Classification de* 100 *Caoutchoucs et Guttaperchas*, and *Classification de* 40 *Savons Végétaux*. These lists, when brought together, will prove serviceable to all those interested in the application of plants.

THE phenomenon of fluorescence, according to M. Lallemand (*Journal de Physique*) is much more general than has been commonly supposed; he knows of only two substances in which it is *nil*, viz., rock-salt and quartz. If it has not been remarked in the majority of liquids, and even of transparent solids which possess it, this is because all the spectral rays are capable of producing it, and the fluorescence, instead of being produced with a maximum of brightness and a proper colour at the surface of incidence, is manifested throughout the mass of the body traversed by the light and without a very pronounced proper colour. M. Lallemand distinguishes two kinds of fluorescence—one called *isochromatic*, or of equal colour, in which each simple ray excites an identical vibratory movement; this kind is produced by all the luminous rays of the spectrum in sulphide of carbon, benzine, alcohol, ether, &c., and in water itself in a slight degree; the other is that long observed in sulphate of quinine, and which is therefore called *quinic* or *hypochromatic* fluorescence. Each luminous ray here produces a fluorescence of less refrangibility, with this peculiarity, that a simple light produces often a complex fluorescence, containing rays of various refrangibilities, but always inferior to that of the exciting ray. It is generally the most refrangible and the chemical rays which develop quinic fluorescence of various intensities. A body may possess both kind of fluorescence at once, but the two parts of the spectra corresponding to them may be very unequal. In glass and crystal, *e.g.*, the red, yellow, and green rays develope a weak isochromatic fluorescence, the others produce quinic fluorescence.

M. GIFFARD, the celebrated aeronaut, and inventor of the *injecteur*, is constructing, at Forges-de la-Seine, a small steamboat for service from Pont Royal to the Exhibition (1878) Pier, distance only three miles. The steamer will realise the extraordinary velocity of forty-five miles per hour, and run the distance in four or five minutes. The length of the steamer will be thirty metres, and transverse section three and a half metres.

THE additions to the Zoological Society's Gardens during the past week include six Greek Partridges (*Caccabis saxatilis*) from Persia, Naran River, two Black-headed Partridges (*Caccabis melanocephala*), a Hey's Partridge (*Caccabis heyi*) from Hedyar, near Mecca, presented by Mr. F. M. Burke, Commander S.S. *Arcot*; a Yellow-lored Amazon (*Chrysotis xantholora*) from Central America, purchased.

SCIENTIFIC SERIALS

Poggendorff's Annalen der Physik und Chemie, Ergänzung Band viii., Stück I.—On the electric conductivity of water and some other bad conductors, by M. Kohlrausch.—The mica-combination of Reusch, and the optical rotatory power of crystals, by M. Sohncke.—On determination of the constants for absorption of light in metallic silver, by M. Wernicke.—The interference of refracted light, by M. Lommel.—The fundamental principles of Edlund's electrodynamics, by M. Chwolson.—Volumetric chemical studies, by M. Ostwald.—On the influence of the funnel-valve on electric spark discharges in air, by M. Holtz.—On an electrical fly-wheel like that of the radiometer, by M. Holtz.—Steam-jet air-pump, by M. Teclu.

Journal de Physique, December.—Measurement of the calorific intensity of the solar radiations and of their absortion by the terrestrial atmosphere, by M. Crova.—On various theories given to explain the movements of Crookes's radiometer (second paper), by M. Lippmann.—On the illumination of transparent and opaque bodies (concluded), by M. Lallemand.

THE *Jahrbuch der k.k. geologischen Reichsanstalt zu Wien* (vol. xxvi. part 2), to which are added Dr. Gust. Tschermak's *Mineralogische Mittheilungen* (vol. vi., part 2), contain the following papers:—Geological survey of the Dutch East Indian Archipelago, by Dr. Schneider.—The saline springs of Galicia, by Mich. Kelb.—Report on the volcanic events during the year 1875, by Dr. C. W. C. Fuchs. Of this we publish a detailed account in our "Notes."—On the green slates of Lower Silesia, by Ernst Kalkowsky.—On beryl from Eisvold, in Norway, by M. Websky.—Chemical analysis of the iodiferous saline springs of Darkau, by E. Ludwig.—On the volcanic formations of the Galapagos Islands, by F. A. Gooch.—On a perfect combination of pyrites and hæmatite crystals, by Dr. C. Hintze.—On some minerals from North-western Silesia, by F. Nenimar.

SOCIETIES AND ACADEMIES

LONDON

Chemical Society, December 18, 1876.—Prof. Abel, F.R.S., president, in the chair.—Prof. W. N. Hartley made a communication entitled "a further study of fluid cavities," in which he described the results of his examination of a large number of topaz and of rock sections, mostly granites and porphyries. The fluid contained in the cavities was almost invariably water, but it was very remarkable that the cavities often took the form of the crystals in which they were contained, and nearly always arranged themselves symmetrically with regard to the faces of the crystal.—A paper by Dr. H. E. Armstrong, F.R.S., on thymoquinone, one on high melting points with special reference to those of metallic salts, part 2, and another on the determination of urea, by Mr. G. Turner, followed this, after which Dr. G. Bischof called attention to the rapid corrosion of the so-called "compo" pipe employed by gas-fitters when used to convey water, especially when exposed alternately to the action of air and water.

Meteorological Society, December 20, 1876.—Mr. H. S. Eaton, M.A., president, in the chair.—Rev. C. C. Chevallier, T. Gordon, and Rev. T. H. Quelch were elected Fellows of the Society.—The following papers were read:—On observations with the psychrometer, by Dr. R. Rubenson (translated from the Swedish, and abridged by Dr. W. Doberck). This paper contains an account of the instructions issued to the Swedish observers in order to obtain trustworthy results from the psychrometer, or dry and wet bulb hygrometer. These instructions, however, do not differ from those followed by English observers at the present time.—Contributions to hygrometry: The wet bulb thermometer, by William Marriott, F.M.S. This paper contains the results of observations made with several wet bulbs in different positions and under different conditions, which were carried on in order to determine what a *wet bulb thermometer should be*. Ten thermometers were used as wet bulbs and three as dry bulbs. With three wet bulbs the water receptacles were placed at different angles; but it was found that the readings were not affected by the position of the water receptacle. Others were used with different thicknesses of muslin and conducting threads; but it was shown that the thermometers with the thinnest muslins always gave the lowest readings. Three pairs of dry and wet bulbs were used, one with a closed water reservoir six inches from the dry bulb, the other two having open reservoirs which were respectively three inches and one inch from the dry bulbs. It was found that the dry bulbs of the two latter read lower than the former in fine dry weather, but when the air was damp and during rain they generally read higher. The wet bulbs of the latter read a little higher than the former; this was mostly the case in damp weather. In conclusion, the author submitted for adoption certain regulations for the management of the dry and wet bulb thermometers, in order to secure comparable results.—Visibility, by the Hon. Ralph Abercromby, F.M.S. Visibility, or unusual clearness and nearness of distant objects, is a very trustworthy prognostic of rain in this and many other countries. The usual explanation that much moisture increases the transparency of the atmosphere is not borne out by observation. In this country great nearness occurs on a clear, brisk day, when hard masses of cloud shade the glare of the sky from crossing direct light sent from distant objects, and make clearness so great as to give the impression of nearness. The kind of rain which immediately follows nearness is in short sharp showers, but unsettled weather often follows later. The synoptic conditions of nearness in this country are either straight isobars or the edge of anticyclones, neither of which are associated with settled weather.—Description of a meteorographic model, a letter from the late Commodore M. F. Maury, Hon. Mem. M.S., to Capt. H. Toynbee, F.R.A.S.

Physical Society, December 16, 1876.—Prof. G. C. Foster, president, in the chair.—The following candidate was elected a member of the Society:—Mr. W. Baily, M.A.—Mr. Crookes described some of the most recent results he has obtained in his experiments on the radiometer, and exhibited many beautiful forms of the apparatus, most of which have been devised with a view to decide on the correct theory of the instrument. We shall refer to the subject of the paper in an early number.—Prof. Dewar exhibited a simple electrometer which he has designed, founded on the discovery of Leipman that the capillary constant is not really independent of the temperature or condition of the surface, but is a function of the electromotive force. If a capillary tube be immersed in mercury, and dilute sulphuric acid be placed in the tube above the mercury, and a current from a Daniell's cell be so passed through the liquids that the mercury forms the negative pole, the column will be depressed to an extent dependent on the diameter of the tube. In making an electrometer, Prof. Dewar has increased the sensitiveness by connecting two vessels of mercury by means of a horizontal glass tube filled with the metal, except that it contains a bubble of dilute acid. The tube must have an internal diameter of two millimetres, and it is essential that it be perfectly clean, uniform in diameter, and horizontal. The instruments exhibited were constructed by Messrs. Tisley and Spiller, and Prof. Dewar showed that it is possible by means of them to measure an electromotive force equal to $\frac{1}{10000}$th of a Daniell's cell; forces capable of decomposing water must be measured by causing two currents to act against each other. The index bubble is brought to zero by uniting the mercury cups by a wire. The apparatus is very convenient, as it requires no preparation and is extremely simple in its action. He then showed an instrument arranged by Mr. Tisley for producing a current by the dropping of mercury from a small orifice into dilute sulphuric acid; if the vessel containing the mercury and the acid be connected by a wire a current is found to traverse it. He then exhibited a manometer suitable for measuring very slight variations of pressure, and he illustrated the use of it for proving Laplace's law that the internal pressure multiplied by the diameter of a soap-bubble is constant. It consists of a U-tube, one arm of which is about 15 inches long, and is bent horizontally and levelled with great care. If the shorter arm be connected with a tube on which a bubble has been blown and the diameter of the bubble be varied, the position of the extremity of the alcohol column will be found to vary in accordance with the above law.

Entomological Society, December 6, 1876.—Sir Sidne Smith Saunders, C.M.G., vice-president, in the chair.—Prof. Eduard Grube, Director of the Zoological Museum of the University of Breslau, and Dr. Katter of Putbus, in the Island of

Rügen, were elected foreign members.—Mr. M'Lachlan (on behalf of Mr. W. Denison Roebuck, of Leeds) exhibited some locusts, a swarm of which had passed over Yorkshire during last autumn. He believed that they belonged to the *Pachytylus cinerascens*, an insect which was supposed to breed in some parts of Northern Europe.—Mr. W. C. Boyd exhibited living larvæ of *Brachycentrus subnubilus* in their quadrilateral cases, having been reared from the eggs. They were of a much larger size than those previously exhibited by him at the meeting of November, 1873, being more than half an inch long.—Mr. S. Stevens (on behalf of Mr. Edwin Birchall) exhibited a specimen of *Cirrhœdia xerampelina*, var. *unicolor*, *Agrotis lucernea*, var. *latens*, and what appeared to be a small variety of *Zygæna filipendulæ* with the pupa case and cocoon. They were all taken by Mr. Birchall in the Isle of Man.—Mr. Meldola referred to a request made by Mr. Riley, of St. Louis, Missouri, that entomologists should supply him with cocoons of the parasite *Microgaster glomeratus*, which were much wanted in America to destroy the numerous broods of *Pieris rapæ* which had been imported into that country. Mr. M'Lachlan had at a subsequent meeting stated that *M. glomeratus* was parasitic on *P. brassicæ*, but doubted whether it ever attacked *P. rapæ*; and Mr. Meldola now exhibited the insects he had found parasitic on these two species, that on *P. rapæ* being *Pteromalus imbutus* (one of the *Chalcididæ*), while on *P. brassicæ* he had observed *Microgaster glomeratus* and a dipterous species *Tachina augusta*. Specimens of all of these were exhibited.—Mr. Smith remarked that he had received a nest of *Osmia muraria*, sent to him from Switzerland, in which he had found in one of the cells a yellow larva, which ultimately proved to be that of a beetle belonging to the *Cleridæ* (*Trichodes alvearius*).—Sir Sidney Saunders exhibited a large box of insects of all orders, which had been collected in Corfu by Mr. Whitfield. —Mr. C. O. Waterhouse remarked on the "Catalogus Coleopterorum" of Gemminger and v. Harold, the concluding portion of which was now published. The total number of generic names given is 11,618, of which 7,364 are adopted genera, and 4,254 appear as synonyms. The total number of species recorded is 77,008. Dejean's first Catalogue, published in 1821, gave 6,692 species, while that of 1837 (the 3rd edition) gave 22,399 species, of which, however, only a portion were then described. Taking into consideration the number of species described during the publication of the Munich Catalogue, the number of described species at the present date could not be less than 80,000. Thus, since 1821, the known species of Coleoptera had increased twelvefold.—Sir Sidney Saunders exhibited several larvæ of *Meloïdæ* in their first stage, received from M. Jules Lichtenstein, of Montpellier, including (1) the primary larval form of *Sitaris colletes* found on *Colletes succincta*, feeding on ivy blossoms; (2) the same larval stage of *Mylabris melanura* obtained from the egg, and furnished with triple tarsal appendages like other larvæ of *Meloïdæ* in their primary form; (3) the exuviæ of the primary form of *Meloë cicatricosus* (from the egg), and also the second stage of the same larva, still bearing legs; (4) the primary larva of *Meloë proscarabæus* (?) differing from the foregoing in the structure of the antennæ, taken on an Andrena; (5) the corresponding larval stage of *Meloë autumnalis* (?), also differing as aforesaid, taken on *Scolia hirta*.—Mr. C. O. Waterhouse read descriptions of twenty new species of Coleoptera from various localities.

Geologists' Association, December 1.—Mr. William Carruthers, F.R.S., president, in the chair.—On the comparative ages of the English and Scottish coal-fields, illustrated by the geology of the Lothians and Fifeshire, and the structure and age of Arthur's Seat, Andrew Taylor, F.C.S. The author, after alluding to the early interest evoked by the geological problems which a study of Arthur's Seat suggests, proposed to bring forward some local sections bearing on the question of its age. A section, beginning with the Burdiehouse limestone quarries at East Calder, deals with upwards of 1,700 feet of strata. This area had undergone much disturbance; the trap-sheets were shown to fill the crevices, consequent on the subsidence, both in the main lines of shrinkage and in the parallel ones; nor does this shrinkage and contemporaneous emission of volcanic matter terminate in the lower strata. The structure of the Torbane hill mineral basin proves this. Another section was described at North Queensferry, through what was originally supposed to have been a compact mass of intrusive dolerite. During the earlier operations no igneous rock was touched; it was only towards the close of the work that the narrow plug became visible. The superposition of the beds cut through is —3. Sandstone, 2. Shale, 1. Freshwater (Burdiehouse) limestone. The freshwater limestone was found only in the plug of the tunnel, standing almost vertically, and having a white crystalline character. Below it occurred a bed of ozokerite, three inches thick. The shale near the plug lost its fissile laminated character, assuming a somewhat columnar form. Whilst the dolerite on the hill is visibly crystalline, at the plug it presents a compact aphanitic mass. We have here, as elsewhere, the association of ozokerite and bitumen with limestone.

PARIS

Academy of Sciences, December 18, 1876.—Vice-Admiral Paris in the chair. The following papers were read:—Note on the integration of total differential equations, by M. Bertrand.—Theorems concerning couples of segments taken the one on one tangent of a curve, and the other on an oblique of another curve, and making together a constant length, the curves being of any order and class, by M. Chasles.—On the secular displacements of the plane of the orbit of the eighth satellite of Saturn (Japhet), by M. Tisserand. If we consider on the sphere great circles representing the orbit of Saturn and his ring, and draw through their intersection two great circles suitably chosen, the orbit of the satellite will form with these two latter circles a triangle of constant surface.—Microscopic study of the volcanic rocks of Nossi-Bé, by M. Velain.—Method of methodic compression and immobilisation, by M. Chassagny. A solid inextensible envelope with a caoutchouc bag under it incloses the region to be compressed (*e.g.* a limb), and the bag is injected with air or water.—On a particular class of left unicursal curves of the fourth order, by M. Appel.—Manometer for measuring high pressures, by M. Cailletet (already noticed in connection with the *Journal de Physique*).—Researches on mannite with regard to its optical properties, by MM. Müntz and Aubin. Mannite, of whatever origin, presents the same optical properties.—On the keel of least resistance, by M. Béléguic.—Various notes on Phylloxera.—Calculation of three observations of the new star of Cygnus, by M. Schmidt. —Preliminary note on photographs of stellar spectra, by Dr. Huggins. He submitted a copy of the photographed spectrum of Vega (α Lyræ), in which are seven broad lines, two of them coinciding with the two lines of hydrogen in the solar spectrum.—Observations on the explanation of the phenomenon of the black drop at the moment of exterior contact of Venus and the sun, by M. van de Sande Backhuyzen. —Second note on the theory of the radiometer, by Mr. Crookes.—On an arrangement for reproducing Foucault's experiment (stoppage of a turning disc under the action of an electro-magnet), with the aid of the syren, by M. Bourbouze. The copper disc is fixed on the axis of the syren, and when the magnet is made the sound suddenly stops.—Practical method of testing an element of a battery, by M. Leclanché. He states some interesting effects of variation of temperature on a Daniell element.—Note on the presence of sugar in the leaves of beets, by M. Corenwinder.—Note on a rapid means of determination of lime in presence of magnesia, and on the application of magnesia to the defecation of saccharine juices, by MM. Bernard and Ehrmann.—On the fall of cold air which produced the disastrous frost in the middle of April, 1876, by M. Barral. This he considers strongly in favour of M. Faye's theory.—Absorption, by a meadow, of the fertilising principles contained in a liquid charged with manure and employed in watering, by M. Leplay.—On the quantity of rain that fell and was collected during the heaviest showers, from 1860 to 1876, by M. Berigny. The average of water which fell in ten to forty-five minutes, in the heaviest showers, was 0·51 mm. per minute, which would give 1·53 cc. for thirty minutes (an exceptional case occurred on August 2, 1866, when a shower furnished, in ten minutes, 11·62 mm. of water, equivalent to 1·16 mm. per minute).—Relations between the optical elements of Arthropoda and those of certain worms, by M. Chatin.—On the beds of fossil bones of Pargny Filain and of Dezanne.—M. Decharme described an experiment with coloured rings. Directing a current of vapour of bromine, iodine, or sulphydrate of ammonia against a metallic plate, he obtains, by chemical process, coloured rings similar to the thermal rings he got with a jet of flame.

BERLIN

German Chemical Society, *November* 13, 1876.—A. W. Hofmann, president, in the chair.—O. Pettersson has determined the atomic volumes of isomorphous mixtures of selenates and sulphates, notably of the alumns, containing both acids.—A. Horstmann published researches on the tension of dissociation, proving that the presence of one of the constituents of a substance liable to dissociation diminishes this tension.—V. Meyer described a simple apparatus to show the increase in weight by the combustion of a candle.—Friedrich Müller described simple apparatus for the lecture-room to determine the density of gases and the quantity of water formed by the combustion of hydrogen. The same chemist has determined the temperatures to which solutions of different salts are raised by a current of steam.—C. Hensgen has treated the sulphates of potassium, sodium, and lithium with hydrochloric acid gas at high temperatures, transforming them into chlorides. Sulphate of copper absorbs under similar circumstances 2HCl; heated in a current of air, this (molecular?) compound yields chlorine and water, and reproduces sulphate of copper. These experiments are interesting with regard to Deacon's process.—H. Iobst has found in coto-bark a new base, called by him para-cotoin.—C. Böttinger has treated racemic acid, $C_3H_4O_3$ with hydrocyanic and hydrochloric acids, transforming it into lactic acid as well as into a new acid of the formula $C_7H_{10}O_7$, or $C_7H_8O_7$.—C. Vogel showed absorption-bands produced by magnesia and alumina in solutions of purpurine; by their means traces of these substances can be recognised in the presence of large quantities of organic substances, as in milk, urine, tartaric acid, &c.—C. A. Martius reported on the Chemical Exhibition at Philadelphia.

November 27, 1876.—A. W. Hofmann, president, in the chair.—E. Baumann described phenylsulphate of potassium, obtained by the reaction

$$\underset{\text{Potassic phenate.}}{C_6H_5OK} + \underset{\text{Potassic pyrosulphate.}}{K_2S_2O_7} = \underset{\text{Potassic phenylsulphate.}}{C_6H_5SO_4K} + \underset{\text{Potassic sulphate.}}{K_2SO_4},$$

a well-defined crystalline salt easily decomposed into phenol and sulphuric acid. Conjointly with E. Herter Mr. Baumann proved the transformation of phenoles into phenolsulphates by the digestion in warm-blooded animals.—A. Atterburg described chlorides obtained from α and β dinitronaphthalenes, and expounded the probable reasons of their isomerism.—W. Thörner reported on some derivatives of phenyl-toluyl-ketone.—T. Hunats described citrate of methyl $C_3H_4(OH)(CO_2CH_3)_3$, acetyl-citrate of methyl $C_3H_4(OC_2H_3O)(CO_2CH_3)_3$, the product of the action of PCl_5 on the former, viz., $C_3H_4Cl(CO_2CH_3)_3$, monochloro-tricarballylate of methyl; and experiments trying in vain to produce ethyl-citrate of ethyl.—H. Willgerodt stated that α-dinitrochlorobenzol yields with acetamide (and alcohol) ortho-para-nitraniline (and acetic ether). With urea it yields another dinitraniline.—L. F. Nilson described double nitrites of platinum with K, Na, Li, Rb, Ag, Ca, Sr, Ba, Pb, Mg, Mn, Co, Ni, Fe, Zn, Hg, Be, Al, Cr, In, Y, Er, Ce, La, and Di.—C. Liebermann proved frangulic acid to be identical with emodine $C_{14}H_8O_4 + 1\frac{1}{2}H_2O$. The same chemist showed glass tubes profoundly attacked and rendered non-transparent by water at 200°.—A. Michael and Th. Norton, by treating resorcine with terchloride of iodine, have obtained teriodo-resorcine.

December 11, 1876.—A. W. Hofmann, president, in the chair.—E. Berglund, who obtained imido-sulphonate of ammonium, $NH.(SO_2.ONH_4)_2$, by treating chlorosulphuric acid, $ClSO_2.OH$, with ammonia, has found that by boiling the same with baryta, it yields the barium salt of amido-sulphonic acid, $NH_2.SO_2OH$.—S. Stein described levers, thermometers, and circular measures of rock crystal.—W. Thörner described an apparatus for distilling in vacuo, permitting the change of the receiver without taking the apparatus to pieces.—H. Landolt published interesting details of a projecting apparatus used by him for lecture-purposes.—F. v. Lepel communicated his observations on spectroscopic reactions of magnesium salts.—E. Glatzel described titanic sulphates derived from TiO_2 and Ti_2O_3.—E. Erlenmeyer has observed that an acid phosphate of lime, $CaH_4(PO_4)_2H_2O$, when treated with less water than is necessary for its solution, is decomposed into insoluble dicalcium phosphate, $CaHPO_4 + (H_2O)_2$, and free phosphoric acid. The same chemist recommends the following easy method for preparing cyanides, viz., to fuse ferrocyanide of potassium with sodium—

$$C_{12}N_{12}Fe_2K_8 + Na_4 = (CyK)_8 + (CyNa)_4 + Fe_2.$$

The same chemist, by oxidising normal oxycapronic acid, $C_6H_{12}O_3$, obtained normal valerianic acid.—E. Fischer has transformed diphenylamine into diphenyl-nitrosamine, and the latter into $(C_6H_5)_2N-NH_2$, diphenyl-hydrazine, isomeric with hydrazobenzol, but not transformable into benzidine.—C. Böttinger confirmed former observations that citraconic acid and its isomers treated with nascent hydrogen yield the same pyruvic acid.—A. Laubenheimer reported on orthodinitrochlorobenzol; one of the NO_2 groups having been replaced by NH_2, it yielded, by treatment with nitrite of ethyl, paranitrochlorobenzol.—H. Limpricht published detailed researches on various bromobenzolsulphonic acids.—G. Krämer to purify methylic alcohol transforms it into formiate. The impurity found in the pure alcohol of commerce is dimethyl-acetal. Conjointly with Grotzky he has found in impure methylic alcohol: aceton, dimethyl acetal, allylic alcohol, methyl-ethyl-ketone, higher ketones and oils which with chloride of zinc yielded cymol and xylol.—H. Bulk published simple contrivances to replace the ordinary suction-pump and separating funnel.—C. Liebermann and O. Burg have made researches on braziline, to which they give the formula $C_{16}H_{14}O_5 + H_2O$; the formula of haematoxyline being $C_{16}H_{14}O_6$. Brasiline, when oxidised, yields the colouring matter brasileine, $C_{16}H_{12}O_5$.—A. Frank gave a warning against the use of glass for sealed tubes, that yield more than 1 per cent. of soluble matter to water. He also mentioned that wine bottles are now in use that yield alkali to the wine, thereby spoiling their taste.

VIENNA

I. R. Geological Institution, November 26, 1876.—The Director, M. F. v. Hauer, referred briefly to M. F. Fötterle, vice-director of the institution, who died last summer; he then welcomed M. R. Drasche, who has recently returned from his travels in the Philippine Islands, Japan, and North America. The following papers were read:—Dr. Stache on the old eruptive rocks from the region of the Ortler Mountains; these bear a strong resemblance to modern andesites, and he showed their distribution on a large-scale map. The name of Ortlerite was proposed for one sort of these rocks, with a dioritic dark-coloured cement, a more basic nature, and of an older geological period; for the newer one, with a light-coloured trachytic and more acidic cement, the name of Guldenite was adopted. Many specimens which he presented contain various enclosures of other crystalline rocks.—Dr. E. Majsisovics presented the detailed geological map of South-Eastern Tyrol and the province of Belluno. The mapping was performed in the years 1874–1876, under the direction of the reporter, assisted by Dr. Hörnes and Dr. Dölter, since appointed professors at the University of Graz.—Dr. Tieze, on the country of Krasnowodsk, on the eastern coast of the Caspian Sea, which he had visited on his return from Persia. He stated that the supposition of a reappearance of the Persian-Armenic salt-beds in these parts, was erroneous. The large gypsum beds in Kubadagh belong to the mesozoic formations, and might be contemporaneous with the Jurassic gypsum-beds of Daghestan. The hills of Krasnowodsk may be regarded as a continuation of the Caucasian Mountains, and form the northern part of an anticlinal, whose southern part is partly formed by the Turcomanic Balkan.—Dr. Koch, on the occurrence of ice-crystals in loose gravel which he had observed at the Arlberg.—Dr. Drasche mentioned a similar occurrence that he had noticed during his travels in high mountainous regions of the tropical zone.

FERMENTATION

Études sur la Bière. Par M. L. Pasteur. (Paris: Gauthier-Villars).

I.

IN a recent notice of an article on Brewing contributed by Mr. Pooley to Stanford's "British Manufacturing Industries," some statistics were quoted showing the gigantic development which the production of beer has acquired in the United Kingdom. The amount of beer manufactured in the British Islands, vast though it be, forms yet but a small portion of that made throughout the world. Probably no industry—saving agriculture—employs so large an amount of capital as that of brewing and the various industries supported by it. Important though this old and at present vastly extended industry be, it is yet one which, until very recently, scientific methods of investigation had done but little to add to our knowledge of the complex phenomena underlying the apparently simple art, and therefore even less in preventing the serious losses constantly occurring even with the most careful manufacturer.

The valuable contribution to our knowledge of the biological aspect of fermentation, which M. Pasteur has just given to the world, is a worthy sequel to the classical researches described by the illustrious chemist in the papers read before the French Academy during the last fifteen years, and summarised by him in a popular form in his "Études sur le Vin," and "Études sur le Vinaigre." These important works, containing the results of long years of laborious and brilliant research, have done much to remove the charge brought against science, and have indeed become to the brewer and wine-grower as the brightening sky to the mariner groping his way in fog and uncertainty to his haven. The grateful recognition of twenty years fruitful labour is due alike from practical and scientific men to the illustrious investigator of the Biology of Fermentation, and he certainly will not deem it the less hearty and sincere if occasional exception here or elsewhere be taken to some of his propositions.

Before considering Fermentation and the recent views promulgated by Pasteur and others regarding the interesting and complex phenomena grouped under this term, it will be useful to discuss the changes produced in the malting and mashing processes of the brewer as necessary precursors to the greater change produced in Fermentation properly so-called. Let us, then, examine the change brought about by the action of water and heat on the grain of any of our common cereals—barley, for example; if this be ground and digested for a few hours at a temperature of 60° C. with five or six times its weight of water, it will be found that the whole, or nearly the whole—this depending upon the comparative activity of the albuminous matters present—of the insoluble starch will be changed into products soluble in water. By the agency of the albuminous ferments or alterative agents water will be assimilated and dextrine and Glucose and products of transformation intermediate between these will be obtained.

This reaction is general, and applies not only to the grain of our common cereals, but also to other stored-up amylaceous vegetable products. While, however, the agency of heat and moisture suffice to bring about this remarkable change, it yet requires too much time, and the products formed are not well adapted to the brewer's wants. Various albumenoid bodies, such as the ptyalin in the saliva, and those in the secretions from the pancreas and intestinal canal in the animal economy intensify the action of the soluble albumenoids in ordinary bread-stuffs, and hence produce a greater hydration, and therefore solution, in a given time. Now the object of malting is to convert some of the inert albumenoids into these more active agents of change, and thus the maltster avails himself of a property existing throughout all vegetable tissues, whereby previously stored-up insoluble amylaceous matter is converted, through the joint agency of moisture, heat, and albumenoid ferments, into soluble sugars, and used along with soluble albumenoid matters for the production of new tissues.

To produce an increase in the albumenoid ferments in barley—the grain chiefly employed in England—the maltster first steeps the grain in water for a period varying from fifty to seventy hours according as the skin is thin or thick, that is, more or less pervious to water. So soon as the desired amount of water has been absorbed, it is removed from the cistern and spread out on the floor of the malt-house, the temperature best suited for the production of sound malt being about 15° C. The germination of the grain commences and is allowed to proceed, with occasional turnings, until the plumule of the young growing plant has advanced far enough up the back of the grain to satisfy the objects which the brewer may have in view. Thus, if a full and somewhat dextrinous ale be required, the plumule is barely allowed to grow to the bend, or *bridge*, of the grain, whereas, if a dry alcoholic ale be required, the growth is allowed to proceed further. According to the growth of the plumule, so does the production of active ferment vary. This point being obtained, the malt is placed on the floor of a kiln, whereby further growth is stopped. Without dwelling with too much detail on this malting, or germinating, process, it will be useful to consider here some of the changes produced. In the first place, by the absorption of water the grain swells and the albumenoid ferments previously existing in the grain are made soluble, and these, by the aid of moisture and heat, begin to act on the starch. Meanwhile, a portion of the insoluble albuminous bodies are rendered soluble, and aid in this conversion of starch, and at the same time, in conjunction with the transformation products of starch, serve to build up the cell structures of the growing plumule and rootlets. Throughout the germinating process carbonic acid and heat are evolved precisely as in the subsequent process of the conversion of sugar into alcohol. The analogy does not, however, rest here, because alcohol is also produced in small quantities. If the growing grain be shut in an air-tight vessel, it will be found that as the growth of the young plant is stopped, the amount of alcohol becomes largely increased, attended at the same time by the production of a large quantity of gas, the chief constituent being carbonic acid. This production of alcohol by vegetable cells has already been noticed in the case of fruits by Lechartier and also by Pasteur. The enormous volume of carbonic acid gas produced without the intervention of *free* oxygen is a fact of great interest to which we must again refer when considering the action of yeast upon sugar.

In this germinating process we have an example of the way in which insoluble matter stored up, whether in the seed or in the tissues of a plant, becomes digested and used for the production of fresh tissues. This property is not limited to vegetable organisms; in animals, also, we find stored-up matter, fatty or amylaceous, acted upon by albumenoid ferments, and being thus rendered soluble, become available for the building up of fresh structures, or for the production of heat by their oxidation in the system. It would lead us too far to discuss here the manner and the agents by which albuminous food, such as flesh meat, cheese, &c., are made soluble in the human economy. Suffice it here to state that the means by which nature produces the desired end of solution in animal and vegetable alike, are moisture, heat, and albumenoid ferments.

The following analyses by Oudemans show the changes produced in the malting process and in the subsequent drying on the kiln :—

	Barley.	Malt.		
	Air dried.	Air dried.	Kiln dried (pale).	Kiln dried (amber).
Torrefaction products	0·0	0·0	7·8	14·0
Dextrine	5·6	8·0	6·6	10·2
Starch...	67·0	58·1	58·6	47·6
Sugar	0·0	0·5	0·7	0·9
Cellulose	9·6	14·4	10·8	11·5
Albuminous Substances	12·1	13·6	10·4	10·5
Fatty ,, ...	2·6	2·2	2·4	2·6
Ash, &c.	3·1	3·2	2·7	2·7
Total	100·0	100·0	100·0	100·0

These analyses, though made some years since, and differing in some points from our existing knowledge, are yet sufficient for our present purpose. We see that the air-dried malt, when compared with the barley from which it was made, is poorer in starch, and richer in woody fibre.

Again, as regards the changes in the albuminous bodies, still quoting Oudemans, we find—

	Barley.	Malt.
Gluten, soluble in alcohol	0·28	0·34
Albuminous substances coagulable by heat	0·28	0·45
,, ,, not coagulable ...	1·55	2·08
Insoluble albumen	7·59	6·23
Total	9·70	9·10

We notice that there has been a loss of some of the albuminous matters in the germinating process, but at the same time an increase in the soluble or active agents of change, to obtain which the malting process is followed. Let us now examine the changes which the malt undergoes when placed in the brewer's mash tun and submitted to the action of heat and water. In England the amount of water employed varies with the nature of the beer to be made, it may be taken, however, as being about twice the weight of the malt, and the temperature of the mixture of malt and water varies from 63° C. to 67° C. In the course of half-an-hour the insoluble starch is converted into soluble sugars and dextrine. The infusion thus obtained is, however, too dextrinous in character for the production of dry alcoholic ales, but as the process continues, more and more water is assimilated, and finally an infusion is obtained rich in alcohol-yielding sugars.

Many theoretical explanations have been given, and will doubtless yet be given, as to the action and the products formed. We are indebted to the admirable and suggestive researches of O'Sullivan for the first clear exposition of what takes place, or rather of one of the changes which occur. He formulates the reaction thus :—

$$\underset{\text{Starch}}{C_{18}H_{30}O_{15}} + H_2O = \underset{\text{Dextrine}}{C_6H_{10}O_5} + \underset{\text{Maltose}}{C_{12}H_{22}O_{11}},$$

and he states that this is the final action of soluble ferments on starch. This equation, however, expresses only what takes place when a small quantity of malt acts on starch paste at a temperature of only 40° C. to 45° C. We must rather assume the probability of several changes, of which that formulated by O'Sullivan is one. Thus if the amount of starch be large in comparison to the active albumenoid ferments, and if the water and time of infusion be lessened, we obtain a solution having a reducing power on Fehling's liquid equal to 33 per cent. of glucose. On the other hand, if the conditions be reversed, that is, if we increase the time, the amount of ferment, and the water, we obtain an infusion having a reducing power equal to 66 per cent. of glucose.

Here, however, the action ceases, and the so-called diastase of malt is unable to carry on the hydration beyond the point last-mentioned, where we obtain a solution which reduces Fehling's liquid to the extent of two-thirds of the reduction obtained when the starch is fully hydrated by weak mineral acids.

Formulating the reactions according to the Fehling reducing products obtained we should have—

$$\left\{\begin{array}{l} \underline{C_{12}H_{20}O_{10} + 2H_2O} \\ C_{12}H_{20}O_{10} \\ C_{12}H_{20}O_{10}\,; \end{array}\right.$$

this product having a 33·33 per cent. reducing action. On the other hand, where we continue the action of diastase for a longer period and with more water, we have—

$$\left\{\begin{array}{l} \underline{C_{12}H_{20}O_{10} + 2H_2O} \\ \underline{C_{12}H_{20}O_{10} + 2H_2O} \\ C_{12}H_{20}O_{10}\,; \end{array}\right.$$

this product having a 66·66 per cent. reducing power, and being apparently the final action of diastase on starch. When the hydration of the starch is effected by dilute acid we obtain—

$$\left\{\begin{array}{l} \underline{C_{12}H_{20}O_{10} + 2H_2O} \\ \underline{C_{12}H_{20}O_{10} + 2H_2O} \\ C_{12}H_{20}O_{10} + 2H_2O\,; \end{array}\right.$$

that is, dextrose having the full reducing action.

O'Sullivan's dextrine-maltose reaction might similarly be thus expressed—

$$\left\{\begin{array}{l} \underline{C_{12}H_{20}O_{10} + H_2O} \\ \underline{C_{12}H_{20}O_{10} + H_2O} \\ C_{12}H_{20}O_{10} \end{array}\right.$$

and giving a product having a 44·44 per cent. reducing action. If this be a correct expression it follows that there are two other possible cases where one and three molecules of water are assimilated. Cane-sugar and lactose are isomeric with O'Sullivan's maltose, and are all dextro-rotatory. These three sugars of the formula $C_{12}H_{22}O_{11}$ are all further hydrated by the action of diastase, yeast water, and dilute acids.

Though ignorant of the molecular weights of starch we may yet safely assume in the expression $(C_6H_{10}O_5)_n$ that the value of n must be large, and that a molecule of such complexity will yield in addition to dextrine several sugars isomeric with sucrose and with dextrose, and it may be others of greater hydration. In the brewer's mash tun the hydration products vary according to the malt employed and the extent to which the malting process is pushed before the kiln drying action, the more of the active ferment formed the greater the hydration in a given time. The amount of water is an important factor in the hydration process; the greater this is within certain limits the greater the hydration; and lastly, the products vary with the amount of time given to the mashing or hydration fermentation.

Thus we may briefly sum up the changes produced by the statement that the infusion products of starch will be more dextrinous, *i.e.*, least altered according as we lessen the time, the amount of water, and the growth of the plumules in the malting process; and on the other hand the infusion products will be richer in Glucose (dextrose), and therefore attenuate lower in the subsequent fermentation process, according as we increase the amount of water, the time of infusion, and the growth of the plumule. The variations in these directions introduced in the mashing process in English breweries are within a narrow range, and the products formed have a reducing action on Fehling's liquid, varying from 50 per cent. to 55 per cent. of the total hydration possible by the aid of mineral acids.

The use of unmalted grain is prohibited in England, whereas cane-sugar and Glucose (made by the action of dilute acid on grain) are allowed. The variations in the direction of dextrine-increase were until recently very limited, but on the other hand those in the direction of alcohol-yielding sugars are without limit.

Messrs. O'Sullivan and Valentin, in a communication to the Society of Arts (March 17, 1876), have recently shown how the action of dilute sulphuric acid may be so regulated as to obtain O'Sullivan's dextrine-maltose reaction already described.

The hydration by the agency of very dilute sulphuric acid is carried on until the liquid has a rotatory power of + 171°, indicating two parts of maltose (rotatory power + 150°) and one part of dextrine (rotatory power according to O'Sullivan + 213°), *i.e.*,

$$\frac{2 \times 150 + 213}{3} = + 171^\circ.$$

So soon as the polariscope indicates O'Sullivan's reaction to be complete, the further hydration is stopped by the addition of chalk. Should the mixture of dextrine and maltose thus made prove to yield a stable and good-keeping beer, they will have contributed greatly to counteract the evil tendency of recent legislation by which beer more and more alcoholic has been manufactured.

Having briefly examined the hydration of starch by albumenoid alterative ferments in the brewer's mash-tun, we have now to consider the breaking up of the still complex saccharine products of the reaction into bodies of simpler structure, such as alcohol and carbonic acid, which result from the fermentation process properly so called. Though it is with alcoholic fermentation, with its characteristic boiling or disengagement of carbonic acid gas, that we have chiefly to do, at the same time other products of the decomposition of saccharine bodies, such as acetic, lactic, and butyric acids, must necessarily be considered before we can obtain a correct insight into the phenomena which present themselves in the manufacture of beer.

Let us then follow the products formed by the hydration of starch already studied.

The *wort*, as the brewer terms the liquid containing the infusion products of the mash tun, is drawn off from the insoluble matters of the malt, and is then boiled in another vessel along with hops; the amount of this valuable agent of preservation employed depending upon the strength of the wort, the nature of the product desired, and the length of time it has to be kept before being consumed.

By mere boiling, some of the albuminous bodies are rendered insoluble, a further portion is precipitated by the tannin of the hops, and the resulting liquid, being thus deprived of some of the albuminous food materials, is found to be less liable to subsequent destructive changes. The hops at the same time yield a pleasant bitter principle, and essential oils which play no slight part in the preservation of the manufactured beer. Now, unlike the juice of the grape, the infusion of malt is so rich in albuminous matters, that every expedient is adopted to diminish these aids to destruction; hence the process of boiling, the use of tannin, and the employment in the infusion process of hard water containing salts of lime. To its water Burton chiefly owes its reputation for good ale. The boiled wort, when cooled, is placed in fermenting vessels, and *yeast* is added. This addition of yeast is almost universal; at the same time it must be noted that in the production of *Faro* and *Lambick* the Belgian brewer adds no ferment; a similar practice was at one time rather common in England, and is even now occasionally to be found in Wiltshire. In thus adding no ferment, the brewer follows the invariable practice of the wine-maker, who leaves the must or pressed juice to spontaneous fermentation; the wine-grower may reasonably reckon upon a definite decomposition of his must, but the brewer who follows this method can foretell but little of the result. We shall presently see why the wine-grower's must and the brewer's wort comport themselves so differently under apparently the same conditions. The spontaneous fermentation of malt wort, even now so little practised, is doomed to be altogether discontinued within but a few years.

The English brewer, having cooled his wort to a temperature varying from 14° C. to 18° C., and having added yeast, the fermentation commences, the heat, unless checked, rapidly rises, and the yeast greatly increases in quantity, the larger portion of which rises to the surface of the liquid. Hence this is termed *top* or surface fermentation, in order to distinguish it from the Bavarian process, in which the yeast sinks to the bottom of the liquid. The temperature of the German *bottom* fermentation varies from 5°·5 C. to 7° C., a temperature that can only be maintained by the employment of large quantities of ice.

The *bottom* and *top* yeasts are probably distinct species. M. Pasteur, however, seems to be in error in stating (p. 190) that the bottom yeast may be distinguished by being less spherical than top yeast. It is true that in London and Edinburgh yeast the cells will be found usually round; hard water, however, such as that at Burton, or artificially made so, yields yeast in which the cells are distinctly ovoid in appearance, resembling very closely Bavarian bottom yeast. M. Pasteur further states (pp. 188 and 192) that the bottom yeast yields a beer of finer flavour, and hence argues the replacement of ales produced by top fermentation by those made on the Bavarian system. Here surely he must be thinking rather of the inferior products of the surface fermentation in France and Germany than of those of England and Scotland. His assertions (pp. 12–17) that by bottom fermentation store beers can be produced, whereas those produced by top fermentation must be consumed at once and cannot be transported are certainly strange to an Englishman.

So far from these unfavourable comparisons being true in all cases, the exact opposite is generally the case. Bavarian and other bottom fermentation beers are in fact those which can neither be preserved nor transported without the liberal employment of ice; even that sent from Vienna to London must be kept cold artificially in order to avoid rapid destruction. As regards flavour, there are many who think a glass of Burton pale ale or of good old college rent ale to be superior to any Bavarian beer. The chief cause of the decline in the production of top fermentation beers on the Continent has been the want of attention in the fermentation process, whereas the English brewer, especially the brewer of high-class ales, has been unremitting in his attention to the temperature in fermentation and to the perfect cleansing of the ale. Now where such attention is given it is not difficult to obtain ales which will keep a few years. While objecting to our English produce being so hastily depreciated by M. Pasteur, our brewers will be the first to avail themselves of his biological researches in order to render their produce more stable and better flavoured, without having recourse to the general adoption of the vastly more costly system of bottom fermentation.

Let us now leave this question of the respective value and future development of the two systems of fermentation, and assume that by either the one process or the other we have obtained our glass of beer. The question now naturally presents itself to us, as to others before us, to what is fermentation due? Pasteur's answer to this I propose to discuss next week.

CHARLES GRAHAM

OUR BOOK SHELF

Manual of the Vertebrates of the Northern United States. By David S. Jordan, M.D. (Chicago: Jansen, McClurg, and Co., 1876.)

THIS useful work contains a short diagnostic account of the whole of the vertebrated animals of the Northern United States, and has been written, as the author tells us, to give collectors and students who are not specialists a ready means of identifying the families, genera, and species described. The mammals as well as the birds of North America have been so ably and elaborately treated of by Prof. Baird, Dr. Coues, and others, that those who are studying these branches of zoology will not find this smaller volume of special service, nevertheless we are not acquainted with any work having a range of treatment which includes the reptilia, amphibia, and fishes with the two other classes. The sub-kingdom, as well as each class and order, are concisely defined, and the most modern arrangement is adopted, based upon the best authorities, the relative importance of the characterising features being clearly brought forward. The system of employing artificial keys so useful in botanical determinations, and so successfully employed by Dr. Coues in ornithology, is employed throughout the book, and will, no doubt, be found to work well. A glossary of the principal technical terms used in the body of the book is also appended. As an example of the manner in which the different species are described, we will take that of one of the species of Fly-catchers: "*Empidonax acadicus* (Gm.), Baird. SMALL GREEN-CRESTED FLY-CATCHER.—Clear olive-green; wing bands buffy; whitish becoming yellowish below; yellowish ring about eyes; bill pale below; primaries nearly an inch longer than secondaries; second, third, and fourth primaries nearly equal, and much longer than first and fifth; first much longer than sixth; L. 6; W. 3; T. 2¾; Ts. ⅝; Tcl. ½; E.U.S. frequent." To naturalists on this side the Atlantic the work will be found a valuable one of reference on account of its inclusiveness, and a glance through it makes us feel how useful a similar one on the British vertebrate fauna would prove to students and collectors.

The Emigrant and Sportsman in Canada. By John J. Rowan. (London: Stanford, 1876.)

THIS is a capital book in many respects. Mr. Rowan is himself an old Canadian settler and knows the country well in various aspects. He tells the plain truth as to the suitability of Canada as a field for emigration, and the intending emigrant could not get a better guide as to the resources of the country, and the kind of settlers for which it is adapted. Mr. Rowan is a keen sportsman and has a fair knowledge of zoology. His descriptions of hunting life in Canada are thoroughly interesting and abound with fresh information on the many animals which are still to be found there. Mr. Rowan is a good observer, and some of the information which he gives regarding the animals with whose habits he is familiar may be new even to naturalists. He describes, at considerable length, especially, the habits of the beaver as observed by himself, and adduces some facts to show that previous popular statements with regard to this animal must be to some extent modified. The volume will be found [illegible] interest not only to the emigrant, the sportsman and the naturalist, but to all who love good hunting and trapping stories well told. Its principal defect is the want of an index.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*]

On a Mode of Investigating Storms and Cyclones

I SCARCELY know anything more interesting in connection with the investigation of cyclones and of our storms than the theoretical investigations of Reye, Mohn and Guldberg, and the practical ones of Mr. Clement Ley. Mr. Ley's papers in the *Journal* of the Scottish Meteorological Society, iv. 66, 149, 33[illegible] have especially attracted my attention. We have to study the form of the craters, as I might call them, of the barometric depressions, and their steepness in different directions.

The following note has some connection with this inquiry, and I beg you, if you think it suitable, to give it a place in your esteemed journal :—

In 1874 I proposed to lay, as well as it can be done, a plane or planes, having such a slope as would represent the barometric height at some two distant places, and to indicate (in geodetic terms) the fall and strike, or the inclination on the horizon and the azimuth of the projection of the perpendicular on such a plane, and I still recommend it. In the Netherlands, where my area is small (see Jour. Scot. Met. Soc., iv. 25) it is always easy to find such a plane, and of course its perpendicular. Now I have inquired whether the projection of that perpendicular moved round the horizon generally in a direct way (with the sun) in the same manner as M. Dove has found that the direction of the wind does, and which I demonstrated in *Pogg. Ann.*, lxviii. 417, 553, to be the case thirteen times per annum in our latitude.

On examination I find that in 1874 and 1875 the projection has gone round the horizon in a direct way ten times more than the opposite way ; further, that it often goes back when the direction of the projection lies to the south-east, but that when it has veered to be to the north-west it veers forward surely and quickly enough in a direct way to the east, which is in accordance with the fact that when we have a depression over Ireland or Scotland it then moves in the direction of Norway and Finland. I don't think it superfluous to call the attention of others to this research, and I propose to calculate the results for other years in this respect, which is easily done by means of the Netherlands' *Annuaires*, and thus find thrice a day the direction and size of the steepest gradient.

Utrecht, December 23, 1876 Buys Ballot

Mind and Matter

The problem, "How consciousness stands related to the material organism," has been attempted to be solved by Mr. Duncan, under the head of "Mind and Matter" (Nature, vol. xv., p. 78). Now that a more exact scientific examination has reconciled so many differences on this question, a return to the old *à priori* method of mere logic is still perfectly legitimate, provided the logic is sound.

Admitting that consciousness is *related* to matter, and without contending, for the present, that it may not be a *state* of matter (under certain restrictions of the term), I will content myself with pointing out what seem to be fallacies in this "solution." "It is as easy," says Mr. Duncan, "to predicate subjectivity (susceptibility to consciousness) of one entity called matter as of another entity called soul or spirit. It is no more difficult to conceive of matter being subjective than of spirit being subjective." Let us see if this is or is not petitio principii. It was the difficulty, real or apparent, of ascribing certain attributes (mental) to matter, that demanded the supposition of some support other than material. So that when we say that spirit is alone susceptible to consciousness, we merely express that matter is not thus susceptible. Therefore, to affirm that the one may be as susceptible to consciousness as the other is to assume, *in limine*, that matter may be susceptible to consciousness, the very probability which has to be established.

Mr. Duncan next asserts that "How energy is related to matter in all its forms, is no less mysterious than how subjectivity may be a property of matter." Now every opponent of materialism admits that how energy is *related* to matter is a mystery, and avows that he cannot conceive of consciousness as a *property* of matter ; but the difficulty of understanding the *how*, even if we grant it equal in both cases, cannot establish any parity of probability as to the facts ; for while we know as a fact that energy is *related* to matter, we do not know as a fact that subjectivity (susceptibility to consciousness) is a *property* of matter. And even if we put the argument more exactly, and affirm that we know that subjectivity, like energy, is *related* to matter, still nothing in point is gained, seeing that while we know *all* matter in relation to energy, it is only a certain form of matter (the human) which we *know* to be related to subjectivity ; for if we surmise this of a dog, we cannot *know* it till he tell us.

The next position, "Energy may be divided. Why not subjectivity?" would seem to demand nothing less than absolute proof, since subjectivity, or the state of the Ego, appears indivisible in virtue of its essential unity. Yet no support is advanced except the foregoing assertion, which we have seen is a mere assumption on the side of materialism, and which we shall next see contains an admission all but fatal to the cause it advocates. When Mr. Duncan says, "How energy is related to matter is no less mysterious than how subjectivity may be a property of matter," he admits that we cannot understand either, while he believes the first because it is a fact. But why should we believe the last? Because we cannot understand it, and because it is not a fact? Will he admit that we have advanced any proof of an oyster being an astronomer, when we have affirmed that this would be no more mysterious than the relation of energy to matter? Yet his three remaining arguments go on this ground : they assume that the probability of subjectivity being a property of matter equals the fact of energy being related to matter.

Rugby J. L. Tupper

Solar Physics at the Present Time

At the conclusion of his letter of the 1st inst. (Nature, vol. xv. p. 196), Sir G. B. Airy alludes to a paper of mine as being cited by me (in my last letter to Nature) as being "in the 'Philosophical Transactions.'"

The paper referred to *ought*, with little doubt, to have appeared there, but it did not, and I was most careful to avoid implying that it had ; my words being with regard to it (see your pages 157 and 158) :—

1st, "which I had the honour of communicating to the Royal Society of London *six* years ago ;" and

2nd, "that paper of six years ago, and still in the hands of the Royal Society ;"

nor is there any mention of the "Philosophical Transactions" throughout. Piazzi Smyth,

Edinburgh, January 5 Astronomer Royal for Scotland

Towering of Birds

Snipe frequently tower—also pigeons. I saw a mallard that flew nearly half a mile, towered, and, fell dead. Teal also tower, but their towering is different to the ordinary, as they are as often alive as dead when they fall. I have also remarked this in widgeons, and once in a partridge. In the latter case birds fell right and left, the second a towerer. It was in heavy turnips that had been planted when mangel had missed. The towerer fell on an isolated mangel ; when picked up, he was at least ten yards from the mangel and still alive. Some years ago there was a discussion on this subject in *Land and Water* or the *Field*, and I think it was shown it was due to pulmonary hæmorrhage. At least I was quite aware of the cause, and that head or spine injuries had nothing to do with it.

Ovoca, Ireland G. H. Kinahan

Rooks Building at Christmas

On Christmas morning I saw a few rooks engaged in building in a clump of elms near my house. Four nests are now in progress, though the gale of December 30 made the rooks desist from their work. During the ten years (about) that I have watched their proceedings, I think I have never seen these birds begin building till February.

I may add that our well-watered lands and woods are being visited with wild duck, teal, peewits, and gulls in great numbers. C. M. Ingleby

Valentines, Ilford, Essex

Are We Drying Up?

The above question has been asked in the columns of Nature. As a small contribution towards an answer, it may be stated that at this place the two last years, 1875 and 1876, have been the two wettest in a series of twenty-four years.

In 1875, the rainfall was 44·05 inches.
In 1876 ,, ,, 42·42 ,,

The average of twenty-four years has been 33·11 inches.

Clifton, January 7 George F. Burder

Radiant Points of Shooting Stars

In December, from observations of 163 shooting stars seen in 20¼ hours' watching, chiefly in the evenings, I amply confirmed several of the positions of radiant points as given in my note (Nature, vol. xv., p. 158), and observed that several of the showers there mentioned were actively continued. The centres, as I gave them, of two of these require revision, as the additional meteors seen in December indicate the radiants with greater precision than the few I had noted in November. The new radiant in Sextans, I now deduce at R.A. 148°, Decl. 2° N., and that at τ Leonis, as near Crater R.A. 165°, Decl. 6° S. The meteors from these new showers are very rapid and white, usually leaving bright streaks for 2 or 3 secs. in their path.

Ashley Down, Bristol, January 2 W. F. DENNING

ALEXANDER BAIN

IT is with much regret that we announce the death of Mr. Alexander Bain, which took place at Glasgow on January 2. To many of our readers his name is perhaps unknown, and yet the inventions of Mr. Bain, made when telegraphy was in its infancy, were of the very highest importance. They were perhaps made too soon. Mr. Bain himself never reaped the benefit of them, and would have died in great poverty had it not been for a pension of 80*l.* a year obtained for him from Mr. Gladstone chiefly through the exertions of Mr. C. W. Siemens, Sir William Thomson, and the Society of Telegraph Engineers.

One of the most important services of Mr. Bain to telegraphy was the reinvention of the method of making use of "bodies of natural waters" "to complete the electric circuit by laying a single insulated wire between the given stations, having at each end a metallic brush immersed in the water." In 1838 Steinheil discovered the use of the earth for completing a circuit instead of a return wire, but does not appear to have taken steps to bring his discovery into notice, or to remove the prejudices with which a discovery so startling would naturally be met. Mr. Bain seems to have established the principle for himself, and he published it in a patent of 1841, by Wright and Bain, for "Improvements in applying electricity to control railway engines and carriages, to mark time, to give signals, and to print intelligence at different places." It is impossible to say how large a part of the completeness of our present telegraphic system, particularly of our submarine telegraphic system, is due to this great discovery of Steinheil and Bain.

An early invention by Mr. Bain, was that of the electro-chemical telegraph. This was patented in 1846. Paper chemically prepared is drawn under a metallic style which rubs upon it. As long as there is no current passing in the line the paper comes away from the style unmarked, but each signal sent through the line passes by the style to the prepared paper and leaves a mark. Combinations of dots and dashes, as in the Morse system, formed Mr. Bain's alphabet.

At first the signals were sent by hand by a simple contact key, but Mr. Bain soon found his system capable of receiving signals at far higher speed than that of the fastest hand sending. He was thus led to the invention of automatic methods of transmitting signals of which one is the basis of the most important method at present in use. A slip of paper is perforated with holes arranged in groups, forming the letters required in accordance with the code of signals. This slip is passed between a metallic roller and a contact point. As long as the contact point is separated from the roller by the paper slip, no current passes in the line. But when one of the perforated holes comes under the contact point, the point falls in and makes contact with the metallic roller. The circuit is thus closed, and a signal is sent.

This apparatus was tried before Committees of the Institute and of the Legislative Assembly at Paris. Through a line between Paris and Lille, a message of 282 words was sent. The time taken was fifty-two seconds! The fastest automatic receiving by mechanical instruments of the most refined modern construction, such, for example, as the instruments of Wheatstone, does not commonly reach 100 words per minute. We hear from Sir William Thomson, in his recent address to the British Association, that he *saw* in America "Edison's Automatic Telegraph delivering 1,057 words in 57 seconds—this done by the electro-chemical method of Bain." That Mr. Bain's method was not received in England cannot but be regarded as a great misfortune.

These were, perhaps, Mr. Bain's principal inventions, but there are others of such importance that they well deserve notice. Several of his patents relate to the keeping of time by clocks controlled or driven electrically by a standard clock. Jones' system, now so largely used in England, is based upon the system of Bain. He invented the earth battery in 1843, or rather reinvented it, as Gauss and Steinheil had previously obtained a current, after the discovery by Steinheil of using the earth for a return wire, making one of the earth plates of zinc and the other of copper. In 1844 he patented ingenious apparatus for registering the progress of ships and for taking soundings. Vanes caused to rotate by the motion of the "log" or "sounding fly," through the water were employed, and an electrical method of observing the result on board was employed. The same patent describes apparatus for giving warning when the temperature of the hold of a ship rises above a certain point. An electric circuit was employed, which was closed by the expansion by heat of mercury contained in a tube. The current passing in the circuit traversed coils which formed an electro-magnet. A pointer or alarm connected with the magnet gave the required warning. This method is now very commonly employed for fire alarms; and modifications of it have been proposed for giving warning of over-heating in the bearings of machinery.

He had also an electric method of playing a keyed instrument at a distance on more than one organ or piano at a time; and he applied his perforated paper to the automatic playing of a wind instrument, such as an organ. For this purpose the paper, properly punched, was drawn between the openings of the wind chest and the openings of the notes to be played upon. Whenever and as long as there was a punched hole of the paper between the wind chest and the pipe the note of the pipe sounded. When there was a blank space between the wind chest and pipe the pipe was silent.

In his later years Mr. Bain's inventions have been inconsiderable. Some years ago he was stricken down with paralysis. He died at the age of sixty-six, on the second day of this year, in the Home for Incurables, Broomhill, near Glasgow.

PHOTOGRAPHS OF THE SPECTRA OF VENUS AND α LYRÆ

SINCE the spring of 1872 I have been making photographs of the spectra of the stars, planets, and moon, and particularly among the stars, of α Lyræ and α Aquilæ, with my 28-inch reflector and 12-inch refractor. In the photograph of α Lyræ, bands or broad lines are visible in the violet and ultra-violet region, unlike anything in the solar spectrum. The research is difficult, and consumes time, because long exposures are necessary to impress the sensitive plate, and the atmosphere is rarely in the best condition. The image of a star or planet must be kept motionless for from ten to twenty minutes, and hence the driving-clock of the telescope is severely taxed.

During last summer I obtained some good results, and in October took photographs of the spectrum of Venus which show a large number of lines. I am now studying these pictures, and have submitted them to the inspection of several of my scientific friends, among others, Professors Barker Langley, Morton, and Silliman. There seems to be in the case of Venus a weakening of the spectrum towards H and above that line of the same character as that I have photographically observed to take place in the spectrum of the sun near sunset.

New York, December, 1876 HENRY DRAPER

ON THE STUDY OF BIOLOGY[1]

IT is my duty to-night to speak about the study of Biology, and while it may be that there are many among you who are quite familiar with that study, yet as a lecturer of some standing, it would, I know by experience, be very bad policy on my part to suppose such to be extensively the case. On the contrary, I must imagine that there are many of you who would like to know what Biology is; that there will be others who have that amount of information, but would nevertheless gladly learn why it should be worth their while to study Biology; and yet others, again, to whom these two points are clear, but who desire to learn how they had best study it, and finally when they had best study it; and I shall address myself to the endeavour to give you some answer to these four questions—what Biology is, why it should be studied, how it should be studied, and when it should be studied.

In the first place, in respect to what Biology is, there are, I believe, some persons who imagine that the term "Biology" is simply a new-fangled denomination, a neologism in short, for what used to be known under the title of "Natural History," but I shall try to show you, on the contrary, that the word is the expression of the growth of science during the last 200 years, and came into existence half a century ago.

At the revival of learning, knowledge was divided into two kinds—the knowledge of nature and the knowledge of man; for it was the current idea then (and a great deal of that ancient conception still remains) that there was a sort of essential antithesis, not to say antagonism, between nature and man; and that the two had not very much to do with one another, except that the one was oftentimes exceedingly troublesome to the other. Though it is one of the salient merits of our great philosophers of the seventeenth century, that they recognise but one scientific method, applicable alike to man and to nature, we find this notion of the existence of a broad distinction between nature and man in the writings of Bacon and Hobbes of Malmesbury; and I have brought with me that famous work which is now so little known, greatly as it deserves to be studied, "The Leviathan," in order that I may put to you in the wonderfully terse and clear language of Thomas Hobbes, what was his view of the matter. He says:—

"The register of knowledge of fact is called history. Whereof there be two sorts, one called natural history; which is the history of such facts or effects of nature as have no dependence on man's will; such as are the histories of metals, plants, animals, regions, and the like. The other is civil history; which is the history of the voluntary actions of men in commonwealths."

So that all history of fact was divided into these two great groups of natural and of civil history. The Royal Society was in course of foundation about the time that Hobbes was writing this book, which was published in 1651, and that Society is termed a "Society for the Advancement of Natural Knowledge," which is nearly the same thing as a "Society for the Advancement of Natural History." As time went on, and the various branches of human knowledge became more distinctly developed and separated from one another, it was found that some were much more susceptible of precise mathematical treatment than others. The publication of the "Principia" of Newton, which probably gave a greater stimulus to physical science than any work ever published before, or which is likely to be published hereafter, showed that precise mathematical methods were applicable to those branches of science such as astronomy, and what we now call physics, which occupy a very large portion of the domain of what the older writers understood by natural history. And inasmuch as the partly deductive and partly experimental methods of treatment to which Newton and others subjected these branches of human knowledge, showed that the phenomena of nature which belonged to them were susceptible of explanation, and thereby came within the reach of what was called "philosophy" in those days; so much of this kind of knowledge as was not included under astronomy came to be spoken of as "natural philosophy"—a term which Bacon had employed in a much wider sense. Time went on, and yet other branches of science developed themselves. Chemistry took a definite shape, and as all these sciences, such as astronomy, natural philosophy, and chemistry, were susceptible either of mathematical treatment or of experimental treatment, or of both, a great distinction was drawn between the experimental branches of what had previously been called natural history and the observational branches—those in which experiment was (or appeared to be) of doubtful use, and where, at that time, mathematical methods were inapplicable. Under these circumstances the old name of "Natural History" stuck by the residuum, by those phenomena which were not, at that time, susceptible of mathematical or experimental treatment; that is to say, those phenomena of nature which come now under the general heads of physical geography, geology, mineralogy, the history of plants, and the history of animals. It was in this sense that the term was understood by the great writers of the middle of the last century—Buffon and Linnæus—by Buffon in his great work, the "Histoire Naturelle Générale," and by Linnæus in his splendid achievement, the "Systema Naturæ." The subjects they deal with are spoken of as "Natural History," and they called themselves and were called "Naturalists." But you will observe that this was not the original meaning of these terms; but that they had, by this time, acquired a signification widely different from that which they possessed primitively.

The sense in which "Natural History" was used at the time I am now speaking of has, to a certain extent, endured to the present day. There are now in existence, in some of our northern universities, chairs of "Civil and Natural History," in which "Natural History" is used to indicate exactly what Hobbes and Bacon meant by that term. There are others in which the unhappy incumbent of the chair of Natural History is, or was, still supposed to cover the whole ground of geology and mineralogy, zoology, perhaps even botany in his lectures. But as science made the marvellous progress which it did make at the latter end of the last and the beginning of the present century, thinking men began to discern that under this title of "Natural History" there were included very heterogeneous constituents—that, for example, geology and mineralogy were, in many respects, widely different from botany and zoology; that a man might obtain an extensive knowledge of the structure and functions of plants and animals without having need to enter upon the study of geology and mineralogy, and *vice versâ*; and, further, as knowledge advanced, it became clear that there was a great analogy, a very close alliance, between those two sciences of botany and zoology which deal with living beings, while they are much more widely separated from all other studies. It is due to Buffon to remark that he clearly recognised this great fact. He says: "ces deux genres d'êtres organisés [les animaux et les végétaux] ont beaucoup plus de propriétés communes que de différences réelles." Therefore, it is not wonderful that, at the beginning of the present century, and oddly enough in two different countries, and so far as I know, without any intercommunication, two famous men clearly conceived the notion of uniting the sciences which deal with living matter into one whole, and of dealing with them as one discipline. In fact I may say there were three men to whom this idea occurred contemporaneously, although there were but two who carried it into effect, and only one who worked it out completely. The persons to whom I refer were the eminent physiologist Bichat, the great naturalist Lamarck, in France; and a distinguished German, Treviranus. Bichat[1] assumed the existence of a special group of "physiological" sciences. Lamarck, in a work published in 1801,[2] for the first time made use of the name "Biologie" from the two Greek words which signify a discourse upon life and living things. About the same time, it occurred to Treviranus that all those sciences which deal with living matter are essentially and fundamentally one, and ought to be treated as a whole, and, in the year 1802, he published the first volume of what he also called "Biologie." Treviranus's great merit consists in this, that he worked out his idea, and wrote the very remarkable book to which I refer. It consists of six volumes, and occupied its author for twenty years—from 1802 to 1822.

---

[1] A lecture by Prof. Huxley, delivered at the South Kensington Museum on Saturday, December 16, 1876.

That is the origin of the term "Biology," and that is how it has come about that all clear thinkers and lovers of consistent nomenclature have substituted for the old confusing name of "Natural History," which has conveyed so many meanings, the term "Biology" which denotes the whole of the sciences which deal with living things, whether they be animals or whether they be plants. Some little time ago—in the course of this year, I think—I was favoured by a learned classic, Dr. Field of Norwich, with a disquisition, in which he endeavoured to prove that, from a philological point of view, neither Treviranus nor Lamarck had any right to coin this new word "Biology" for their purpose; that, in fact, the Greek word "Bios" had relation only to human life and human affairs, and that a different word was employed when they wished to speak of the life of animals and plants. So Dr. Field tells us we are all wrong in using the term biology, and that we ought to employ another, only unluckily he is not quite sure about the propriety of that which he proposes as a substitute. It is a somewhat hard one—zootocology. I am sorry we are wrong, because we are likely to continue so. In these matters we must have some sort of "Statute of Limitations." When a name has been employed for half-a-century, persons of authority[3] have been using it, and its sense has become well understood, I am afraid that people will go on using it, whatever the weight of philological objection.

Now that we have arrived at the origin of this word "Biology," the next point to consider is: What ground does it cover? I have said that in its strict technical sense it covers all the phenomena that are exhibited by living things, as distinguished from those which are not living; but while that is all very well so long as we confine ourselves to the lower animals and to plants, it lands us in a very considerable difficulty when we reach the higher forms of living things. For whatever view we may entertain about the nature of man, one thing is perfectly certain, that he is a living creature. Hence, if our definition is to be interpreted strictly, we must include man and all his ways and works under the head of Biology; in which case we should find that psychology, politics, and political economy, would be absorbed into the province of Biology. In fact, civil history would be merged in natural history. In strict logic it may be hard to object to this course, because no one can doubt that the rudiments and outlines of our own mental phenomena are traceable among the lower animals. They have their economy and their polity, and if, as is always admitted, the polity of bees and the commonwealth of wolves fall within the purview of the biologist proper, it becomes hard to say why we should not include therein human affairs, which in so many cases resemble those of the bees in zealous getting, and are not without a certain parity in the proceedings of the wolves. The real fact is that we biologists are a self-sacrificing people; and inasmuch as, on a moderate estimate, there are about a quarter of a million different species of animals and plants to know about already, we feel that we have more than sufficient territory. There has been a sort of practical convention by which we give up to a different branch of science what Bacon and Hobbes would have called "Civil History." That branch of science has constituted itself under the head of Sociology. I may use phraseology which at present will be well understood and say that we have allowed that province of Biology to become autonomous; but I should like you to recollect that that is a sacrifice, and that you should not be surprised if it occasionally happens that you see a biologist trespassing upon questions of philosophy or politics; or meddling with human education; because, after all, that is a part of his kingdom which he has only voluntarily forsaken.

Having now defined the meaning of the word Biology, and having indicated the general scope of Biological Science, I turn to my second question, which is—Why should we study Biology? Possibly the time may come when that will seem a very odd question. That we, living creatures, should not feel a certain amount of interest in what it is that constitutes our life will eventually, under altered ideas of the fittest objects of human inquiry, seem to be a singular phenomenon; but at present, judging by the practice of teachers and educators, this would seem to be a matter that does not concern us at all. I propose to put before you a few considerations which I dare say many of you will be familiar with already, but which will suffice to show—not fully, because to demonstrate this point fully would take a great many lectures—that there are some very good and substantial reasons why it may be advisable that we should know something about this branch of human learning. I myself entirely agree with another sentiment of the philosopher of Malmesbury, "that the scope of all speculation is the performance of some action or thing to be done," and I have not any very great respect for, or interest in, mere knowing as such. I judge of the value of human pursuits by their bearing upon human interests; in other words, by their utility, but I should like that we should quite clearly understand what it is that we mean by this word "utility." Now in an Englishman's mouth it generally means that by which we get pudding or praise, or both. I have no doubt that is one meaning of the word utility, but it by no means includes all I mean by utility. I think that knowledge of every kind is useful in proportion as it tends to give people right ideas, which are essential to the foundation of right practice, and to remove wrong ideas, which are the no less essential foundations and fertile mothers of every description of error in practice. And inasmuch as, whatever practical people may say, this world is, after all, absolutely governed by ideas, and very often by the wildest and most hypothetical ideas, it is a matter of the very greatest importance that our theories of things, and even of things that seem a long way apart from our daily lives, should be as far as possible true, and as far as possible removed from error. It is not only in the coarser practical sense of the word "utility," but in this higher and broader sense that I measure the value of the study of biology by its utility, and I shall try to point out to you that you will feel the need of some knowledge of biology at a great many turns of this present nineteenth century life of ours. For example, most of us lay great and very just stress upon the conception which is entertained of the position of man in this universe and his relation to the rest of nature. We have almost all of us been told, and most of us hold by the tradition, that man occupies an isolated and peculiar position in nature; that though he is in the world he is not of the world; that his relations to things about him are of a remote character, that his origin is recent, his duration likely to be short, and that he is the great central figure round which other things in this world revolve. But this is not what the biologist tells us. At the present moment you will be kind enough to separate me from them, because it is in no way essential to my argument just now that I should advocate their views. Don't suppose that I am saying this for the purpose of escaping the responsibility of their beliefs, because at other times and in other places I do not think that point has been left doubtful; but I want clearly to point out to you that for my present argument they may all be wrong; nevertheless, my argument will hold good. The biologists tells us that all this is an entire mistake. They turn to the physical organisation of man. They examine his whole structure, his bony frame, and all that clothes it. They resolve him into the finest particles into which the microscope will enable them to break him up. They consider the performance of his various functions and activities, and they look at the manner in which he occurs on the surface of the world. Then they turn to other animals and taking the first handy domestic animal—say a dog—they profess to be able to demonstrate that the analysis of the dog leads them, in gross, to precisely the same results as the analysis of the man; that they find almost identically the same bones, having the same relations; that they can name the muscles of the dog by the names of the muscles of the man, and the nerves of the dog by those of the nerves of the man, and that such structures and organs of sense as we find in the man such also we find in the dog; they analyse the brain and spinal cord, and they find that the nomenclature which fits the one answers for the other. They carry their microscopic inquiries in the case of the dog as far as they can, and they find that his body is resolvable into the same elements as those of the man. Moreover, they trace back the dog's and the man's development, and they find that, at a certain stage of their existence, the two creatures are not distinguishable the one from the other; they find that the dog and his kind have a certain distribution over the surface of the world comparable in its way to the distribution of the human species. What is true of the dog they tell us is true of all the higher animals; and they assert that for the whole of these creatures they can lay down a common plan, and regard the man and the dog, and the horse and the ox as minor modifications of one great fundamental unity. Moreover, the investigations of the last three-quarters of a century have proved, they tell us, that similar inquiries carried out through all the different kinds of animals which are met with in nature will lead us, not in one straight series, but by many roads, step by step, gradation by gradation, from man, at the summit, to specks of animated jelly at the bottom of the series; so that the idea of Leibnitz and of Bonnet, that animals form a great scale of being, in which there are a series of gradations from the most complicated form to the lowest and simplest; that idea, though not exactly in the form in which it was propounded by those philosophers, turns out to be substantially correct. More than this, when biologists pursue their investigations into the vegetable world, they find that they can, in the same way, follow out the structure of the plant from the most gigantic and complicated trees down, through a similar series of gradations, until they arrive at specks of animated jelly, which they are puzzled to distinguish from those specks which they reached by the animal road.

---

[1] See the distinction between the "sciences physiques" and the "sciences physiologiques" in the "Anatomie Générale," 1801.

[2] "Hydrogeologie," an. x. (1801).

[3] "The term *Biology*, which means exactly what we wish to express, *the Science of Life*, has often been used and has of late become not uncommon among good writers."—Whewell, "Philosophy of the Inductive Sciences," vol. i. p. 544 (edition of 1847).

Thus, biologists have arrived at the conclusion that a fundamental uniformity of structure pervades the animal and vegetable worlds, and that plants and animals differ from one another simply as modifications of the same great general plan.

Again, they tell us the same story in regard to the study of function. They admit the large and important interval which, at the present time, separates the manifestations of the mental faculties observable in the higher forms of mankind, and even in the lower forms, such as we know them, mentally from those exhibited by other animals; but, at the same time, they tell us that the foundations or rudiments of almost all the faculties of man are to be met with in the lower animals; that there is a unity of mental faculty as well as of bodily structure, and that, here also, the difference is a difference of degree and not of kind. I said "almost all," for a reason. Among the many distinctions which have been drawn between the lower creatures and ourselves, there is one which is hardly ever insisted on,[1] but which may be very fitly spoken of in a place so largely devoted to art as that in which we are assembled. It is this, that while among various kinds of animals it is possible to discover traces of all the other faculties of man, especially the faculty of mimicry, yet that particular form of mimicry which shows itself in the imitation of form either by modelling or by drawing is not to be met with. As far as I know, there is no sculpture or modelling, and decidedly no painting or drawing, of animal origin. I mention the fact, in order that such comfort may be derived therefrom as artists may feel inclined to take.

If what the biologists tell us is true, it will be needful for us to get rid of our erroneous conceptions of man and of his place in nature, and substitute right ones for them. But it is impossible to form any judgment as to whether the biologists are right or wrong unless we are able to appreciate the nature of the arguments which they have to offer.

One would almost think that this was a self-evident proposition. I wonder what a scholar would say to the man who should undertake to criticise a difficult passage in a Greek play but who obviously had not acquainted himself with the rudiments of Greek grammar. And yet before giving positive opinions about these high questions of Biology people not only don't seem to think it necessary to be acquainted with the grammar of the subject, but they have not even mastered the alphabet. You find criticism and denunciation showered about by persons who not only have not attempted to go through the discipline necessary to enable them to be judges, but have not even reached that stage of emergence from ignorance in which the knowledge that such a discipline is necessary dawns upon the mind. I have had to watch with some attention—in fact I have been favoured with a good deal of it myself—the sort of criticism with which biologists and biological teachings are visited. I am told every now and then that there is a "brilliant article"[2] in so-and-so, in which we are all demolished. I used to read these things once, but I am getting old now, and I have ceased to attend very much to this cry of "wolf." When one does read any of these productions, what one finds generally, on the face of it, is that the brilliant critic is devoid of even the elements of biological knowledge, and that his brilliancy is like the light given out by the crackling of thorns under a pot of which Solomon speaks. So far as I recollect Solomon makes use of that image for purposes of comparison; but I won't proceed further into that matter.

Two things must be obvious: in the first place, that every man who has the interests of truth at heart must earnestly desire that every well-founded and just criticism that can be made should be made; but that, in the second place, it is essential to anybody's being able to benefit by criticism that the critic should know what he is talking about and be in a position to form a mental image of the facts symbolised by the words he uses. If not, it is as obvious in the case of a biological argument as it is in that of a historical or philological discussion, that such criticism is a mere waste of time on the part of its author, and wholly undeserving of attention on the part of those who are criticised. Take it then as an illustration of the importance of biological study, that thereby alone are men able to form something like a rational conception of what constitutes valuable criticism of the teachings of biologists.[1]

---

[1] I think that Prof. Allman was the first to draw attention to it.

[2] Galileo was troubled by a sort of people whom he called "paper philosophers," because they fancied that the true reading of nature was to be detected by the collation of texts. The race is not extinct, but, as of old, brings forth its "winds of doctrine" by which the weathercock heads among us are much exercised.

Next, I may mention another bearing of biological knowledge—a more practical one in the ordinary sense of the word. Consider the theory of infectious disease. Surely that is of interest to all of us. Now the theory of infectious disease is rapidly being elucidated by biological study. It is possible to produce from among the lower animals cases of devastating diseases which have all the appearance of our infectious diseases, and which are certainly and unmistakably caused by living organisms. This fact renders it possible, at any rate, that that doctrine of the causation of infectious disease which is known under the name of "the germ theory" may be well-founded; and if so it must needs lead to the most important practical measures in dealing with those most terrible visitations. It may be well that the general as well as the professional public should have a sufficient knowledge of biological truths to be able to take a rational interest in the discussion of such problems, and to see, what I think they may hope to see, that, to those who possess a sufficient elementary knowledge of Biology, they are not all quite open questions.

Let me mention another important practical illustration of the value of biological study. Within the last forty years the theory of agriculture has been revolutionised. The researches of Liebig, and those of our own Lawes and Gilbert, have had a bearing upon that branch of industry the importance of which cannot be over-estimated; but the whole of these new views have grown out of the better explanation of certain processes which go on in plants, and which of course form a part of the subject-matter of Biology.

I might go on multiplying these examples, but I see that the clock won't wait for me, and I must therefore pass to the third question to which I referred:—Granted that Biology is something worth studying, what is the best way of studying it? Here I must point out that, since Biology is a physical science, the method of studying it must needs be analogous to that which is followed in the other physical sciences. It has now long been recognised that if a man wishes to be a chemist it is not only necessary that he should read chemical books and attend chemical lectures, but that he should actually for himself perform the fundamental experiments in the laboratory, and know exactly what the words which he finds in his books and hears from his teachers, mean. If he does not do that he may read till the crack of doom, but he will never know much about chemistry. That is what every chemist will tell you, and the physicist will do the same for his branch of science. The great changes and improvements in physical and chemical scientific education which have taken place of late have all resulted from the combination of practical teaching with the reading of books and with the hearing of lectures. The same thing is true in Biology. Nobody will ever know anything about Biology except in a dilettante "paper-philosopher" way, who contents himself with reading books on botany, zoology, and the like; and the reason of this is simple and easy to understand. It is that all language is merely symbolical of the things of which it treats; the more complicated the things, the more bare is the symbol, and the more its verbal definition requires to be supplemented by the information derived directly from the handling, and the seeing, and the touching of the thing symbolised:—that is really what is at the bottom of the whole matter. It is plain common sense, as all truth, in the long run is only common sense clarified. If you want a man to be a tea merchant, you don't tell him to read books about China or about tea, but you put him into a tea-merchant's office where he has the handling, the smelling, and the tasting of tea. Without the sort of knowledge which can be gained only in this practical way his exploits as a tea merchant will soon come to a bankrupt termination. The "paper-philosophers" are under the delusion that physical science can be mastered as literary accomplishments are acquired, but unfortunately it is not so. You may read any quantity of books, and you may be almost as ignorant as you were at starting, if you don't have, at the back of your minds, the change for words in definite images which can only be acquired through the operation of your observing faculties on the phenomena of nature.

It may be said:—"That is all very well, but you told us just now that there are probably something like a quarter of a million different kinds of living and extinct animals and plants, and a human life could not suffice for the examination of one-fiftieth part of all these." That is true, but then comes the great convenience of the way things are arranged; which is, that although there are these immense numbers of different kinds of living things in existence, yet they are built up, after all, upon marvellously few plans.

There are, I suppose, about 100,000 species of insects, if not more, and yet anybody who knows one insect—if a properly chosen one—will be able to have a very fair conception of the structure of the whole. I do not mean to say he will know that structure thoroughly or as well as it is desirable he should know it, but he will have enough real knowledge to enable him to understand what he reads, to have genuine images in his mind of those structures which become so variously modified in all the forms of insects he has not seen. In fact, there are such things as types of form among animals and vegetables, and for the purpose of getting a definite knowledge of what constitutes the leading modifications of animal and plant life it is not needful to examine more than a comparatively small number of animals and plants.

Let me tell you what we do in the biological laboratory in the building adjacent to this. There I lecture to a class of students daily for about four-and-a-half months, and my class have, of course, their text-books; but the essential part of the whole teaching, and that which I regard as really the most important part of it, is a laboratory for practical work, which is simply a room with all the materials arranged for ordinary dissection. We have tables properly arranged in regard to light, microscopes, and dissecting instruments, and we work through the structure of a certain number of animals and plants. As, for example, among the plants, we take a yeast plant, a *Protococcus*, a common mould, a *Chara*, a fern, and some flowering plant; among animals we examine such things as an amœba, a *vorticella*, and a fresh-water polype. We dissect a star-fish, an earthworm, a snail, a squid and a fresh-water mussel. We examine a lobster and a cray-fish, and a black beetle. We go on to a common skate, a cod-fish, a frog, a tortoise, a pigeon, and a rabbit, and that takes us about all the time we have to give. The purpose of this course is not to make skilled dissectors, but to give every student a clear and definite conception, by means of sense-images, of the characteristic structure of each of the leading modifications of the animal kingdom; and that is perfectly possible, by going no further than the length of that list of forms which I have enumerated. If a man knows the structure of the animals I have mentioned, he has a clear and exact, however limited, apprehension of the essential features of the organisation of all those great divisions of the animal and vegetable kingdoms to which the forms I have mentioned severally belong. And it then becomes possible for him to read with profit, because every time he meets with the name of a structure, he has a definite image in his mind of what the name means in the particular creature he is reading about, and therefore the reading is not mere reading. It is not mere repetition of words; but every term employed in the description, we will say, of a horse or of an elephant, will call up the image of the things he had seen in the rabbit, and he is able to form a distinct conception of that which he has not seen as a modification of that which he has seen.

---

[1] Some critics do not even take the trouble to read. I have recently been adjured with much solemnity, to state publicly why I have "changed" my opinion as to the value of the palæontological evidence of the occurrence of evolution.

To this my reply is, Why should I when that statement was made seven years ago? An address delivered from the Presidential Chair of the Geological Society in 1870 may be said to be a public document, inasmuch as it not only appeared in the *Journal* of that learned body, but was re-published in 1873 in a volume of "Critiques and Addresses," to which my name is attached. Therein will be found a pretty full statement of my reasons for enunciating two propositions: (1) that "when we turn to the higher *Vertebrata*, the results of recent investigations, however we may sift and criticise them, seem to me to leave a clear balance in favour of the evolution of living forms one from another;" and (2) that the case of the horse is one which "will stand rigorous criticism."

Thus I do not see clearly in what way I can be said to have changed my opinion, except in the way of intensifying it, when in consequence of the accumulation of similar evidence since 1870, I recently spoke of the denial of evolution as not worth serious consideration.

I find this system to yield excellent results; and I have no hesitation whatever in saying, that any one who has gone through such a course, attentively, is in a better position to form a conception of the great truths of Biology, especially of morphology (which is what we chiefly deal with), than if he had merely read all the books on that topic put together.

The connection of this discourse with the Loan Collection of Scientific Apparatus arises out of the exhibition in that collection of certain aids to our laboratory work. Such of you as have visited that very interesting collection may have noticed a series of diagrams and of preparations illustrating the structure of a frog. Those diagrams and preparations have been made for the use of the students in the biological laboratory. Similar diagrams and preparations illustrating the structure of all the other forms of life we examine, are either made or in course of preparation. Thus the student has before him, first, a picture of the structure he ought to see, secondly, the structure itself worked out; and if with these aids, and such needful explanations and practical hints as a demonstrator can supply, he cannot make out the facts for himself in the materials supplied to him, he had better take to some other pursuit than that of biological science.

I should have been glad to have said a few words about the use of museums in the study of Biology, but I see that my time is becoming short, and I have yet another question to answer. Nevertheless I must, at the risk of wearying you, say a word or two upon the important subject of museums. Without doubt there are no helps to the study of Biology, or rather to some branches of it, which are, or may be, more important than natural history museums; but, in order to take this place in regard to Biology, they must be museums of the future. The museums of the present do not do by any means so much for us as they might do. I do not wish to particularise, but I dare say many of you seeking knowledge, or in the laudable desire to employ a holiday usefully, have visited some great natural history museum. You have walked through a quarter of a mile of animals more or less well stuffed, with their long names written out underneath them, and, unless your experience is very different from that of most people, the upshot of it all is that you leave that splendid pile with sore feet, a bad headache, and a general idea that the animal kingdom is a "mighty maze without a plan." I do not think that a museum which brings about this result does all that may be reasonably expected of such an institution. What is needed in a collection of natural history is that it should be made as accessible and as useful as possible, on the one hand to the general public, and on the other to scientific workers. That need is not met by constructing a sort of happy hunting-ground of miles of glass cases, and, under the pretence of exhibiting everything, putting the maximum amount of obstacle in the way of those who wish properly to see anything.

What the public want is easy and unhindered access to such a collection as they can understand and appreciate; and what the men of science want is similar access to the materials of science. To this end the vast mass of objects of natural history should be divided into two parts—one open to the public, the other to men of science, every day. The former division should exemplify all the more important and interesting forms of life. Explanatory tablets should be attached to them, and catalogues containing clearly-written popular expositions of the general significance of the objects exhibited should be provided. The latter should contain, packed into a comparatively small space, in rooms adapted for working purposes, the objects of purely scientific interest. For example, we will say I am an ornithologist. I go to examine a collection of birds. It is a positive nuisance to have them stuffed. It is not only sheer waste, but I have to reckon with the ideas of the bird-stuffer, while, if I have the skin and nobody has interfered with it I can form my own judgment as to what the bird was like. For ornithological purposes what is needed is not glass cases full of stuffed birds on perches, but convenient drawers into each of which a great quantity of skins will go. They occupy no great space and do not require any expenditure beyond their original cost. But for the purpose of the public, who want to learn indeed, but do not seek for minute and technical knowledge, the case is different. What one of the general public walking into a collection of birds desires to see is not all the birds that can be got together. He does not want to compare a hundred species of the sparrow tribe side by side; but he wishes to know what a bird is, and what are the great modifications of bird structure, and to be able to get at that knowledge easily. What will best serve his purpose is a comparatively small number of birds carefully selected, and artistically, as well as accurately, set up; with their different ages, their nests, their young, their eggs, and their skeletons side by side; and in accordance with the admirable plan which is pursued in this museum, a tablet, telling the spectator in legible characters what they are and what they mean. For the instruction and recreation of the public such a typical collection would be of far greater value than any many-acred imitation of Noah's ark.

Lastly comes the question as to when biological study may best be pursued. I do not see any valid reason why it should not be made, to a certain extent, a part of ordinary school training. I have long advocated this view, and I am perfectly certain that it can be carried out with ease, and not only with ease, but with very considerable profit to those who are taught; but then such instruction must be adapted to the minds and needs of the scholars. They used to have a very odd way of teaching the classical languages when I was a boy. The first task set you was to learn the rules of the Latin grammar in the Latin language—that being the language you were going to learn! I thought then that this was an odd way of learning a language, but did not venture to rebel against the judgment of my superiors. Now, perhaps, I am not so modest as I was then, and I allow myself to think that it was a very absurd fashion. But it would be no less absurd if we were to set about teaching Biology by putting into the hands of boys a series of definitions of the classes and orders of the animal kingdom, and making them repeat them by heart. That is a very favourite method of teaching, so that I sometimes fancy the spirit of the old classical system has entered into the new scientific system, in which case I would much rather that any pretence at scientific teaching were abolished altogether. What really has to be done is to get into the young mind some notion of what animal and vegetable life is. You have to consider in this matter practical convenience as well as other things. There are difficulties in the way of a lot of boys making messes with slugs and snails; it might not work in practice. But there is a very convenient and handy animal which everybody has at hand, and that is himself; and it is a very easy and simple matter to obtain common plants. Hence the broader facts of anatomy and physiology can be taught to young people in a very real fashion by dealing with the broad facts of human structure. Such viscera as they cannot very well examine in themselves, such as hearts, lungs, and livers, may be obtained from the nearest butcher's shop. In respect to teaching something about the biology of plants, there is no practical difficulty, because almost any of the common plants will do, and plants do not make a mess—at least they do not make an unpleasant mess; so that, in my judgment, the best form of Biology for teaching to very young people is elementary human physiology on the one hand, and the elements of botany on the other; beyond that I do not think it will be feasible to advance for some time to come. But then I see no reason why in secondary schools, and in the Science Classes which are under the control of the Science and Art Department—and which I may say, in passing, have, in my judgment, done so very much for the diffusion of a knowledge over the country—I think that in those cases we may go further, and we may hope to see instruction in the elements of Biology carried out, not perhaps to the same extent, but still upon somewhat the same principle as we do here. There is no difficulty, when you have to deal with students of the ages of 15 or 16, in practising a little dissection and getting a notion, at any rate, of the four or five great modifications of the animal form, and the like is true in regard to plants.

While, lastly, to all those who are studying biological science with a view to their own edification merely, or with the intention of becoming zoologists or botanists; to all those who intend to pursue physiology—and especially to those who propose to employ the working years of their lives in the practice of medicine—I say that there is no training so fitted, or which may be of such important service to them, as the thorough discipline in practical biological work which I have sketched out as being pursued in the laboratory hard by.

I may add that, beyond all these different classes of persons who may profit by the study of Biology, there is yet one other. I remember, a number of years ago, that a gentleman who was a vehement opponent of Mr. Darwin's views and had written some terrible articles against them, applied to me to know what was the best way in which he could acquaint himself with the strongest arguments in favour of evolution. I wrote back, in all good faith and simplicity, recommending him to go through a course of comparative anatomy and physiology, and then to study development. I am sorry to say he was very much displeased, as people often are with good advice. Notwithstanding this discouraging result, I venture, as a parting word, to repeat the suggestion, and to say to all the more or less acute lay and clerical "paper-philosophers"[1] who venture into the regions of biological controversy—Get a little sound, thorough, practical, elementary instruction in biology.

T. H. HUXLEY

EXPERIMENTS WITH THE RADIOMETER

I.

ABSTRACTS of my earlier papers on "Repulsion Resulting from Radiation" having appeared in NATURE, it has been suggested that an account of my later researches, which place the subject in such a different light, may also prove of interest.

It has already been shown that if the air is expelled from a large bulb containing a suspended bar of pith, and a lighted candle is placed about 2 inches from the globe, the pith bar commences to oscillate to and fro, the swing gradually increasing in amplitude until the dead centre is passed over, when several complete revolutions are made. The torsion of the suspended fibre now offers resistance to the revolutions, and the bar commences to turn in the opposite direction. It has been found, however, that very little movement takes place until the vacuum is so good as to be almost beyond the powers of an ordinary air-pump to produce, and that, as the vacuum gets more nearly absolute, so the force increases in power. The most obvious explanation therefore is, that the repulsive action is due to radiation; but at a very early stage of my investigation I found that the best vacuum I had succeeded in producing might contain enough matter to offer resistance to motion, and in describing an experiment in a paper sent to the Royal Society on February 5, 1876, I said that the impression conveyed to my mind was that the torsion beam was swinging in a viscous fluid, and the repulsion caused by radiation was indirectly due to a difference of thermometric heat between the black and white surfaces of the moving body, and that it might be due to a secondary action on the residual gas.

I have recently succeeded in producing such a complete exhaustion that I have not only reached the point of maximum effect, but gone so far beyond it that repulsion nearly ceases, and the results I have thus obtained seem to show conclusively that the true explanation of the action of the radiometer is that given by Mr. Johnstone Stoney, according to which the repulsion is due to the internal movements of the molecules of the residual gas. When the mean length of path between successive collisions of the molecules is small compared with the dimensions of the vessel, the molecules, rebounding from the heated surface, and therefore moving with an extra velocity, help to keep back the more slowly moving molecules which are advancing towards the heated surface; it thus happens that though the individual kicks against the heated surface are increased in strength in consequence of the heating, yet the number of molecules struck is diminished in the same proportion, so that there is equilibrium on the two sides of the discs, even though the temperature of the faces are unequal. But when the exhaustion is carried to so high a point that the molecules are sufficiently few, and the mean length of path between their successive collisions is comparable with the dimensions of the vessel, the swiftly-moving, rebounding molecules spend their forces in part or in whole on the sides of the vessel; and the onward crowding, more slowly-moving molecules are not kept back as before, so that the number which strike the warmer face approaches to, and in the limit equals, the number which strike the back cooler face; and as the individual impacts are stronger on the warmer than on the cooler face, pressure is produced, causing the warmer face to retreat.

Before referring at length to the experiments which led to my adopting the above theory, I will describe some effects of dark heat, &c., on the radiometer. In a paper I sent to the Royal Society on January 5, 1876, and which is now being published in the *Philosophical Transactions* of the Royal Society, about seventeen pages are occupied with the description of my experiments with various forms of this instrument. In the present paper I propose only to refer to a few typical experiments made during the year 1875.

---

[1] Writers of this stamp are fond of talking about the Baconian method. I beg them therefore to lay to heart these two weighty sayings of the herald of Modern Science:—

"Syllogismus ex propositionibus constat, propositiones ex verbis, verba notionum tesseræ sunt. Itaque si notiones ipsæ (*id quod basis rei est*) confusæ sint et temere a rebus abstractæ, nihil in iis quæ superstruuntur est firmitudinis."—"Novum Organon," ii. 14.

"Huic autem vanitati nonnulli ex modernis summa levitate ita indulserunt, ut in primo capitulo Geneseos et in libro Job et aliis scripturis sacris, philosophiam naturalem fundare conati sint; *inter viva quærentes mortua.*"—*Ibid.* 65.

To show the action of dark heat on the radiometer, a candle was placed at such a distance from the instrument that the arms would make one revolution a minute. A small glass flask of boiling water was then placed half-an-inch from the bulb. The revolutions instantly stopped, two of the arms setting equidistant from the hot-water flask. The flask of water was removed. As the portion of the bulb which had been heated by the hot water cooled, the white surface gradually crept nearer and nearer to it, the superior repulsion of the candle on the black discs urging the arms round, and acting in opposition to the repulsion of the hot glass to the white disc. At last the force of the light drove the white disc with difficulty past the hot spot of glass. Rotation then commenced, but for some revolutions there appeared to be a difficulty in the white discs passing the spot of glass which had been warmed by the hot water; and the flask of boiling water being replaced in its position half-an-inch from the bulb of the radiometer, the rotation immediately stopped.

The instrument having become cool, the candle was again placed in position, so that it produced one revolution in a minute. The finger was then pressed against the side of the bulb, and as the spot of glass got warm, the white surface experienced more and more difficulty in getting past it, until at last one refused to pass, and the arms came to rest.

The instrument was again allowed to cool, and the revolutions recommenced at the usual speed (the laboratory in which this was tried was somewhat cold). I then came from a warm room, and stood a foot from the radiometer, watching it. In about a minute the radiant heat from my body had warmed the side of the bulb nearest to me sufficiently to cause an appreciable difficulty in the movement, and soon the revolutions stopped. The same effect has been observed if the radiometer is brought into a very warm room and placed near a cold window. If the daylight is feeble, the instrument not very sensitive, or an observer stands near the instrument, an appreciable sticking is observed as the white discs come near that part of the bulb which is the warmest.

These experiments show that many precautions are necessary to guard against the interfering action of unequal heating of the radiometer when it is being used for accurate measurements.

Having found such an antagonistic action of dark heat, I tried the action of ice. This is equivalent to warming the opposite side of the instrument. A lump of ice was brought within half an inch of the bulb on the opposite side to the candle. The revolutions got slower, until at last the movement stopped altogether, one arm pointing direct to the ice, and being apparently held there by a powerful attractive force. Bringing the candle nearer caused the arms to oscillate a little, and when it was almost close to the bulb the force of the light overcame the action of the ice, and the arms revolved again, but irregularly, and with jerks, the discs moving quickly to the ice and leaving it with difficulty. In this action of ice no preference was noticed for either the black or white surface.

A very delicate radiometer, in 2-inch bulb, was placed in a sufficient light to allow it to be seen distinctly, but not enough to cause it to move. I then came out of a warm room and stood near it. In a few seconds it began to move slowly round in the negative direction, *i.e.* the black discs advanced instead of retreated. On moving away from the instrument the rotation gradually stopped. I again approached it, and held one hand an inch from the bulb. Rotation soon commenced, but still in the reverse way. These experiments were frequently repeated and always with the same results.

When the instrument was at rest I came quickly to it, and gently breathed on the bulb. There was a slight movement in the normal direction, but this stopped directly, and the arms then revolved the reverse way for more than a minute, performing three or four complete revolutions.

A glass shade four inches in diameter was held over a gas-flame till the air inside was warm, and the inner surface dim with steam. It was then inverted over the radiometer. Rotation commenced the reverse way, and kept up for several minutes. The glass shade was then dried inside, and heated uniformly before a fire until it had a temperature of about 50° C. It was then inverted over the radiometer. Reverse rotation instantly commenced, and kept up with some vigour for more than five minutes, diminishing in speed until the shade had cooled down to the temperature of the surrounding air.

The same experiment was repeated, and whilst the arms were in full negative rotation, a lighted candle was slowly brought near it. When three feet off the negative rotation slackened. When the candle was about two feet off the arms became still, and when nearer than two feet the instrument rotated normally, the antagonism between the action of the hot shade and the lighted candle was perfect; by moving the candle to and fro it was easy to cause the radiometer to move in one direction or the other, or to become still.

I now tried the action of a radiometer the moving parts of which were made of a good conductor of heat, such as a metal, instead of pith, which is a bad conductor of heat. I selected thin rolled brass as the material wherewith to make the arms and discs of a radiometer. The parts were all fastened together with hard solder, and no cement or organic matter was used, so that if necessary the instrument could be submitted to a high temperature without injury. The moving portion weighed 13·1 grains. One side of the discs was silvered and polished, the other side being coated with lampblack. The apparatus was exhausted with a charcoal reservoir attached. A candle 1½ inch from the bulb caused it to revolve about once a second, the black surface being repelled in the normal manner.

Standing in a rather dark cold room, it was covered with a warm glass shade, and it immediately began to revolve the negative way, but very slowly. A few drops of ether poured on the bulb caused the arms to move rather rapidly the normal way. A hot shade put over whilst it was thus moving caused it to stop and then begin moving the reverse way. A small non-luminous gas flame was held vertically beneath the apparatus, so that hot air should ascend and wrap round the bulb on all sides. The arms now revolved the reverse way.

The brass radiometer being somewhat heavy, one was made of aluminium, the moving parts being hard soldered as before. A siphon-gauge was attached, and the apparatus connected direct on to the pump by a spiral, no charcoal tube being used. One side of the wings was bright aluminium, and the other was lampblacked. When exhausted the arms revolved very quickly to a candle a few inches off, the black being repelled. On removing the candle the arms stopped and immediately commenced revolving the reverse way, keeping up rotation for more than ten minutes, and being little inferior in speed to what it was when the candle shone on it. The whole of the bulb was heated with a Bunsen burner; whilst it was getting hot the aluminium arms revolved rapidly in the normal direction, but as soon as the source of heat was removed and cooling commenced, rotation set up in the reverse way, and continued with great energy till the whole thing was cold. It appeared as if the reverse movement during the cooling was equal in energy to the normal movement as it was being heated.

A little ether was poured on the bulb of a very sensitive pith radiometer as it was standing still in a faint light. The evaporation of the ether caused a chilling of the instrument and a rapid abstraction of heat from the arms. They commenced to move in the normal direction and increased quickly in speed until they revolved at a rate of one in four seconds. This movement kept up for several minutes, and as it slackened it could at any time be revived by a few drops of ether on the bulb. When in rapid movement a hot glass shade was placed over the radiometer the movement slackened, the arms quickly came to rest and immediately revolved in the reverse direction, acquiring a speed of about two revolutions a minute, and keeping up this reverse movement for more than ten minutes.

I again set the instrument in rapid rotation by dropping ether on the top of the bulb and applied the tip of one finger to the side of the bulb for ten seconds. The rotation stopped, and I could not start it again for some minutes, although I dropped ether on the bulb, several times in the interval. When the radiometer had once more acquired the temperature of the air I dropped ether on the bulb, not in the centre, but so that the ether wetted only half of the bulb. The arm which was nearest to the part most chilled by the ether rushed towards that part and remained, as it were, fixed opposite to it, refusing to move away, although I tried to equalise the temperature by dropping ether on the other parts of the bulb, and to drive it round by bringing a candle near. Not until the candle came within six inches of the bulb did the arms begin to rotate, which they then did with a rush, as if suddenly relieved from a state of tension.

I have referred to a sufficient number of experiments to show that a metal radiometer rotates in a negative direction on being exposed to the action of dark heat, the black advancing and continuing to do so until the temperature has become uniform throughout. On removing the source of heat, the fly commences to revolve with rapidity the positive way, the black this time retreating as it would if light shone on it.

To determine whether at temperatures between 250° and 100° the repellant action of radiant heat was about equal on black and on white surfaces, I used a radiometer having pith discs blackened on one side. A tube was sealed into one side of the bulb, and having two stout platinum wires passing along it, sealed their whole length in glass to prevent leakage of air into the interior of the apparatus. At the ends of the wires a spiral of fine platinum wire was fastened, and the other ends terminated in loops outside. The bulb was perfectly exhausted, and the following experiments were tried :—

A resistance-coil was so adjusted that a battery would keep the platinum spiral at a bright red heat. The arms of the radiometer, which were before quite still, moved rapidly until two of the discs were one on each side of the hot spiral, the black disc being further off than the white disc. The resistance was then gradually increased, and as the temperature of the spiral diminished, the black disc gradually approached the spiral, until, when the temperature was just at the point of visible redness in a dark room, the black and white discs were practically equidistant from the spiral. On diminishing the resistance, the same phenomena took place in inverse order.

The resistance was again adjusted to give a bright red spiral, and the contact key kept pressed down. A lighted match was momentarily brought near the bulb, so as to start a movement. Rotation of the arms commenced, and kept up, with some energy, at the rate of about one revolution in five seconds, equal to that given by a candle eight inches off. There was some little hesitation, as the white side came up to the spiral, but this was scarcely noticed when the speed had become steady. The resistance was now slightly increased. The speed became slower as the temperature of the spiral diminished, and the hesitation, as the white approached the spiral, became more apparent. The resistance was further increased, with the effect of making rotation still slower, bringing the temperature of the spiral down to just visible redness in the dark. The speed of rotation again slackened ; at each approach of the white surface to the spiral it appeared to stop, hesitate, and then get past with a rush. Thus it went on for a few revolutions, until one white disc, a little nearer, perhaps, than the others, was not able to pass, and the arms, after a few oscillations, came to rest, the black and the white surfaces being, as near as I could judge, equidistant from the hot spiral.

I now tried to ascertain whether, at temperatures lower than 100° C., the white would be repelled most.

The resistance of the coil was increased again, and the position of the arms in respect to the spiral noticed. When so much resistance was offered to the passage of the current that the spiral would only be just warm, I fancied the white was further from it than the black, but the observation was not satisfactory at higher temperatures ; up to visible redness the repulsion was equal for each. Breathing on the bulb sent the arms rapidly round the reverse way.

The battery was disconnected from the instrument, and one end of a wire was attached to one of the platinum loops, the other end of the wire being connected to the prime conductor of a frictional electrical machine. A few turns of the handle sent the arms flying about wildly, first in the positive and then in the negative direction, till finally one pointed steadily to the platinum spiral, and refused to move. When the candle was quite close it overcame the interference, and the discs revolved in an irregular jerky manner. In three or four days the electrical disturbance was sufficiently diminished to enable me to proceed with my experiments, but I could detect the influence for weeks after.

One pole of a small induction-coil capable of giving half-inch sparks in air, was fastened to the platinum loops, the other pole being held by an insulating handle. The loose pole was then brought near the bulb. The nearest disc rushed round to it and followed it a little, then it stuck as if the glass were electrified. By gently moving the loose pole round I could get the arms to rotate in either direction, and they would keep on for five minutes or more when once started. These movements appear all to be explained by the known laws of static electricity, the rotations being of the "electrical fly" kind.

I obtained rotation in a radiometer without having the surfaces of the discs differently coloured. One having the pith discs lamp-blacked on both sides, and weighing 1·25 grain, was exhausted with a charcoal tube attached. On a candle being brought near it, the arms moved until two of the discs were equidistant from the flame, and no amount of initial impulse in either direction would set it in rotation. A piece of ice caused it to move until one disc pointed to the ice, when it also stopped, but by shading the candle with a screen, so that the light shone on only one half of the tube, rapid rotation commenced, which, by altering the position of the screen to the other side, was instantly stopped, and changed into as rapid rotation in the opposite direction.

To enable me to exhibit the movement of a radiometer to a large audience I have made an instrument, the discs of which are of thin glass, silvered and polished on one side, and coated with lampblack on the other. Owing to its great weight the movement is somewhat slow, but in the sun, or, with a strong light shining on the instrument, it is very striking, as it shows discs of light chasing each other round the room.

To communicate motion from the interior of the bulb to the outside, a radiometer was made which would carry round a magnet. Outside the bulb of this instrument I suspended, in a vertical position, a smaller magnet having the south pole at the top and the north pole at the bottom ; this oscillates to and fro with every revolution of the radiometer, and making contact at the bottom, carries an electric current from a battery to a Morse instrument through which a ribbon of paper is drawn by clockwork so that at each revolution of the radiometer a record is printed on the strip of paper by dots; close together if the radiometer revolves quickly, farther apart if it goes slower.

The power of the earth on the magnet is too great to allow the radiometer to start without some initial impetus; there should therefore be an astatic combination inside the bulb, but for a single experiment it may be set going by placing a few coils of insulated copper wire outside the bulb and depressing the battery key for an instant. An electric current is thus passed through the coils of wire, and the interior magnet is immediately deflected from its north-south position; the impetus thus gained enables the light to keep up the rotation.

For the purpose of measuring the amount of force exerted by radiation I constructed a torsion balance capable of indicating the millionth of a grain. A light beam having two square inches of pith at one end is balanced on a fine fibre of glass[1] stretched horizontally in a tube, one end of the fibre being connected with a torsion handle passing through the tube, and indicating angular movements on a graduated circle. The beam is cemented to the torsion fibre, and the whole is enclosed in glass and connected with the mercury pump by a spiral tube and exhausted as perfectly as possible. A flat oblong piece of soft iron weighing accurately 0·01 grain is put into the cross tube under the pith surface. This weight can be picked up by a horse-shoe magnet outside the tube and dropped on any part of the pith. A mark is made at the exact centre of the pith surface, and by moving the magnet about it is easy to place the iron weight accurately on this mark. A ray of light from a lamp reflected from a mirror in the centre of the beam to a millimetre scale four feet off shows the slightest movement. When the reflected ray points to zero, a turn of the torsion handle in one direction or the other will raise or depress the pith end of the beam, and thus cause the index ray to travel along the scale to the right or to the left. If a small weight is placed on one end so as to depress it, and the torsion handle is then turned, the tendency of the glass fibre to untwist itself will ultimately balance the downward pressure of the weight, and will again bring the index ray to zero. It was found that when the weight of the 1-100th of a grain was placed on the pith surface the torsion handle had to be turned twenty-seven revolutions and 353°, or 10073° before the beam became horizontal. The downward pressure of the 1-100th of a grain was therefore equivalent to the force of torsion of the glass thread when twisted through 10073°.

I then found out the degree of delicacy of the balance. 1° of torsion gave a very decided movement of the index ray, a torsion of 10073° balancing the 1-100th of a grain, while 100074° overbalanced it. The balance will therefore turn to the 99-100,000,000th of a grain.

Weighed in this balance, the mechanical force of a candle 12 inches off was found to be 0·000444 grain; of a candle 6 inches off 0·001772 grain. At half the distance the weight of radiation should be four times, or 0·001776 grain; the difference between theory and experiment being only four millionths of a grain is a sufficient proof that the indications of this instrument follow rigidly the law of inverse squares. An examination of the differences between the separate observations and the mean shows that my estimate of the sensitiveness of this balance is not excessive, and that in practice it will safely indicate the millionth of a grain.

I performed an experiment at the meeting of the Royal Society on March 30 last to demonstrate the movement of the glass case of the radiometer. I made use of a large radiometer in a 4-inch bulb with ten arms, eight of which were brass, and the other two a long watch-spring magnet. The discs were of pith blackened on one side.

The instrument was floated in a vessel of water, four candles being placed round it to set the arms in rotation. A mark was put on the glass envelope to enable a slight movement to be seen.

A powerful magnet was now brought near the moving arms, which immediately stopped, and at the same time the glass envelope commenced to revolve in the opposite direction to that in which the arms had been revolving. The movement kept up as long as the candles were burning, and the speed was one revolution in two minutes. On the magnet being removed the arms obeyed the force of radiation from the candles and revolved rapidly, whilst the glass envelope quickly came to rest. The candles were then blown out, and as soon as the whole instrument had come to rest, a bar-magnet was moved alternately from one side to the other of the radiometer, so as to cause the vanes to rotate as if they had been under the influence of a candle. The glass envelope moved about one revolution in three minutes in the same direction as the arms, and on reversing the direction of movement of arms, the glass envelope changed direction also. This I consider is proof that the internal friction, either of the steel point on the glass socket or the vanes against the residual air, or of both these causes combined, is considerable. Moving the vanes round by the exterior magnet carries the whole envelope round in opposition to the friction of the water against the glass.

In another communication I propose to give the results of my experiments on the influence of the residual gas on the movement of the radiometer, and also refer to other results which I have recently obtained.

WILLIAM CROOKES

ON A NEW ASTRONOMICAL CLOCK[1]

THE object of this communication was to explain to members of the Association and give them an opportunity of seeing in my house in the University a clock which had been described in a communication to the Royal Society, in 1869, entitled "On a New Astronomical Clock and a Pendulum Governor for Uniform Motion." The following description is taken from the *Proceedings* of the Royal Society for 1869, except a few alterations and additions, and except the drawings, which have not been hitherto published:—

It seems strange that the dead-beat escapement should still hold its place in the astronomical clock, when its geometrical transformation, the cylinder escapement of the same inventor, Graham, only survives in Geneva watches of the cheaper class. For better portable timekeepers it has been altered, through the vicious rack-and-pinion movement, into the superlatively good detached lever. If it is possible to make astronomical clocks go better than at present by merely giving them a better escapement, it is quite certain that one on the same principle as the detached lever, or as Earnshaw's ship-chronometer escapement, would improve their timekeeping.

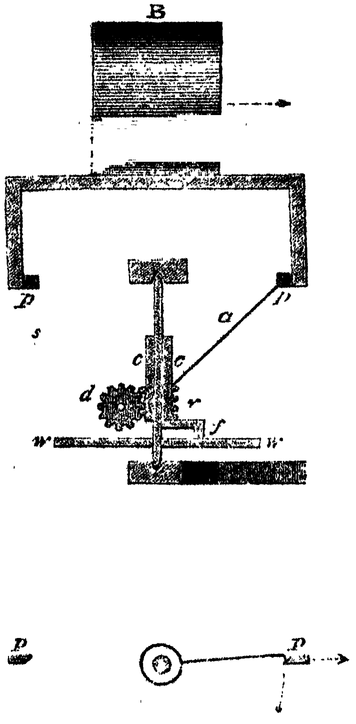
But the irregularities hitherto tolerated in astronomical clocks may be due more to the faultiness of the steel and mercury compensation pendulum, with its loosely attached glass jar, and of the mode in which it is hung, and to instability of the supporting clock-case or framework, than to imperfection of the escapement and the greatness of the arc of vibration which it requires; therefore it would be wrong to expect confidently much improvement in the time-keeping merely from improvement of the escapement. I have therefore endeavoured to improve both the compensation for change of temperature in the pendulum, and the mode of its support, in a clock which I have recently made with an escapement on a new principle, in which the simplicity of the dead-beat escapement of Graham is retained, while its great defect, the stopping of the whole train of wheels by pressure of a tooth upon a surface moving with the pendulum, is remedied.

---

[1] The torsion of fibre must be selected with great care. Ten threads were drawn out before the blowpipe and suspended from a horizontal beam. Weights were then gradually hung on to the lower ends. Only two were found strong enough. The one selected stood 450 grains without breaking, its diameter being less than ·001 inch.

[1] "On a New Form of Astronomical Clock with Free Pendulum and Independently Governed Uniform Motion for Escapement Wheel." By Prof. Sir William Thomson, F.R.S. (Communicated to Section A of the British Association, Thursday, September 7, 1876.)

Imagine the escapement-wheel of a common dead-beat clock to be mounted on a collar fitting easily upon a shaft, instead of being rigidly attached to it. Let friction be properly applied between the shaft and the collar, so that the wheel shall be carried round by the shaft unless resisted by a force exceeding some small definite amount; and let a governor giving uniform motion be applied to the train of wheel-work connected with this shaft, and so adjusted that, when the escapement-wheel is unresisted, it will move faster by a small percentage than it must move to keep time properly. Now let the escapement wheel, thus mounted and carried round, act upon the escapement, just as it does in the ordinary clock. It will keep the pendulum vibrating, and will, just as in the ordinary clock, be held back every time it touches the escapement during the interval required to set it right again from having gone too fast during the preceding interval of motion. But in the ordinary clock the interval of rest is considerable, generally greater than the interval of motion. In the new clock it is equal to a small fraction of the interval of motion: $\frac{1}{800}$ in the clock as now working, but to be reduced probably to something much smaller yet. The simplest appliance to count the turns of this escapement-wheel (a worm, for instance, working upon a wheel with thirty teeth, carrying a hand round, which will correspond to the seconds' hand of the clock) completes the instrument; for minute and hour-hands are a superfluity in an astronomical clock.



In various trials which I have made since the year 1865, when this plan of escapement first occurred to me, I have used several different forms, all answering to the preceding description, although differing widely in their geometrical and mechanical characters. In all of them the escapement-wheel is reduced to a single tooth or arm, to diminish as much as possible the moment of inertia of the mass stopped by the pendulum. This arm revolves in the period of the pendulum (two seconds for a one second's pendulum), or in some odd multiple of it. Thus the pendulum may execute one or more complete periods of vibration without being touched by the escapement. In all my trials the pallets have been attached to the bottom of the pendulum, projecting below it, in order that satisfactory action with a very small arc of vibration (not more on each side than $\frac{1}{100}$ of the radius, or 1 centimetre for the seconds' pendulum) may be secured.

In the clock in my house the seconds' pendulum of the fine movement, vibrates with great constancy through half a millimetre, that is to say, through an arc of $\frac{1}{2000}$ of the radian, on each side of the vertical. This, I believe, is the smallest range that has hitherto been realised in any seconds' pendulum of an astronomical or other clock.

In the drawing *s* represents the vertical escapement shaft, round which is fitted loosely the collar *c*, carrying the worm *v*. The small wheel, *d*, is worked by *v*, and carries round the seconds' hand of the clock. *a* represents a piece of fine steel wire, being the single arm to which the teeth of the escapement-wheel are reduced in the clock described in this paper; *p p* the pallets attached to bars projecting downwards from the bob, B, of the pendulum; *f*, a foot bearing the weight of the collar-worm and escapement tooth. The bar connecting *f* with the collar is of such a length as to give a proper moment to the frictional force by which the collar is carried round. The shaft *s* carries a wheel, represented in section by *w w*, which is driven by a train of wheel-work (not shown in the drawing) from the governor. This wheel is made to go $\frac{1}{3}$ per cent. faster than once round in two seconds, while the pendulum prevents the collar from going round more than once in two seconds.

My trials were rendered practically abortive from 1865 until a few months ago by the difficulty of obtaining a satisfactory governor for the uniform motion of the escapement-shaft; this difficulty is quite overcome in the pendulum governor, which I now proceed to describe.

Imagine a pendulum with single-tooth escapement mounted on a collar loose on the escapement shaft just as described above—the shaft being vertical in this case also. A square-threaded screw is cut on the upper quarter of the length of the shaft, this being the part of it on which the escapement-collar works; and a pin fixed to the collar projects inwards to the furrow of the screw, so that, if the collar is turned relatively to the shaft, it will be carried along, as the nut of a screw, but with less friction than an ordinary nut. Below the screw and long nut-collar, three-quarters of the length of the escapement-shaft is surrounded by a tube which, by wheel-work, is carried round about 5 per cent. faster than the central shaft. This outer shaft, by means of friction produced by the pressure of proper springs, carries the nut collar round along with it, except when the escapement-tooth is stopped by either of the pallets attached to the pendulum. A stiff cross-piece (like the head of a T), projecting each way from the top of the tubular shaft, carries, hanging down from it, the governing masses of a centrifugal friction governor. These masses are drawn towards the axis by springs, the inner ends of which are acted on by the nut collar, so that the lower or the higher the latter is in its range, the springs pull the masses inwards with less or more force. A fixed metal ring coaxial with the main shaft holds the governing masses in when their centrifugal forces exceed the forces of the springs, and resists the motion by forces of friction increasing approximately in simple proportion to the excess of the speed above that which just balances the forces of the springs. As long as the escapement-tooth is unresisted, the nut collar is carried round with the quicker motion of the outer tubular shaft, and so it *screws upwards*, increasing the force of the springs. Once every semiperiod of the pendulum it is held back by either pallet, and the nut-collar screws *down* as much as it rose during the preceding interval of freedom when the action is regular; and the central or main escapement-shaft turns in the same period as the tooth, being the period of the pendulum. If through increase or diminution of the driving-power, or diminution or increase of the coefficient of friction between the governing masses and the ring on which they press, the shaft tends to turn faster or slower, the nut collar works its way down or up the screw, until the governor is again regulated, and gives the same speed in the altered circumstances. It is easy to arrange that a large amount of regulating power shall be implied in a single turn of the nut collar relatively to the central shaft, and yet that the periodic application and removal of about $\frac{1}{30}$ of this amount in the half period of the pendulum shall cause but a *very small* periodic variation in the speed. The latter important condition is secured by the great moment of inertia of the governing masses themselves round the main shaft. My communication to the Royal Society ended as follows:—

"I hope after a few months' trial, to be able to present a satisfactory report of the performance of the clock now completed according to the principles explained above. As many of the details of execution may become modified after practical trial, it is unnecessary that I should describe them minutely at present. Its general appearance, and the arrangement of its characteristic parts, may be understood from the photograph now laid before the Society."

I am sorry to say that the hope here expressed has not hitherto been realised. Year after year passed producing only more or less of radical reform in various mechanical details of the governor and of the fine movement, until about six months ago, when, for the first time, I had all except the pendulums in approximately satisfactory condition. By that time I had discovered that my choice of zinc and platinum for the temperature compensation, and lead for the weight of the pendulums, was a mistake. I had fallen into it about ten years ago through being informed that in Russia the gridiron pendulum had been reverted to because of the difficulty of getting equality of temperature throughout the length of the pendulum; and without stopping to perceive that the right way to deal with this difficulty was to face it and take means of securing practical equality of temperature throughout the length of the pendulum (which it is obvious may be done by simple enough appliances), I devised a pendulum in which the compensation is produced by a stiff tube of zinc and a platinum wire placed nearly parallel each to the other throughout the length of the pendulum. The two pendulums of the clock shown to the British Association were constructed on this plan. Now it is clear that the materials chosen for compensation should, of all those not otherwise objectionable, be those of greatest and of least expansibility. Therefore, certainly, glass or platinum ought to be one of the materials, and the steel of the ordinary astronomical mercury pendulum is a mistake. Mercury ought to be the other (its cubic expansion being six times the linear expansion of zinc) unless the capillary uncertainty of the mercury surface lead to irregular changes in the rate of the pendulum. The weight of the pendulum ought to be of material of the greatest specific gravity attainable; at all events unless the whole is to be mounted in an air-tight case; because one of the chief errors of the best existing pendulums is that depending on the variations of barometric pressure. The expense of platinum puts it out of the question for the weight of the pendulum, even although the use of mercury for the temperature compensation did not also give mercury for the weight. Thus even though as good compensation could be got by zinc and platinum as by any other means, mercury ought on account of its superior specific gravity (nearly three times that of lead) to be preferred to lead for the weight of the pendulum.

I have accordingly now made several pendulums (for tide-gauges) with no other material in the moving part than glass and mercury, and with rounded knife edges of agate for the fixed support; and I am on the point of making four more for two new clocks which I am having made on the plan which forms the subject of this communication. I have had no opportunity hitherto of testing the performance of any of these pendulums, but their action seems very promising of good results, and the only untoward circumstance which has hitherto appeared in connection with them has been breakages of the glass in two attempts to have one carried safely to Genoa for a tide-gauge made by Mr. White, to an order for the Italian Government.

As to the accuracy of my new clock, it is enough to look at the pendulum vibrating with perfect steadiness, from month to month, through a range of half a centimetre on each side of its middle position, with its pallets only touched during $\frac{1}{300}$ of the time by the escapement-tooth, to feel certain that, if the best ordinary astronomical clock owes any of its irregularities to variations of range of its pendulum or to impulses and friction of its escapement-wheel, the new clock must, when tried with an equally good pendulum, prove more regular. I hope soon to have it tried with a better pendulum than that of any astronomical clock hitherto made, and if it then shows irregularities amounting to $\frac{1}{10}$ of those of the best astronomical clocks, the next step must be to inclose it in an air-tight case kept at constant temperature, day and night, summer and winter.

ON THE TROPICAL FORESTS OF HAMPSHIRE[1]

ENGLAND at the present time has a climate far from tropical, but at the time to which this lecture refers the palm and spice plants flourished here; and hence the climate then may rightly be spoken of as actually tropical.

The data on which this inference is based are the fossil leaves which are found in the clays of the south of Hampshire. Out of the many thousands of such leaves obtained by me during summer holidays for many years past, some selected specimens were exhibited in a cabinet in the Loan Collection of Scientific Instruments. Other collections of leaves from this spot and from Alum Bay have been made, and may be seen in the British Museum. It is the district immediately along the line east and west of Bournemouth which has been specially examined, and it is in the lower Bagshot beds, which are, comparatively speaking, amongst the youngest of the geological scale, that the leaves referred to have been found.

These Bagshot beds need not detain us; but as I have referred to them as amongst the youngest in the geological scale, I may mention that above them we have the Bracklesham beds, full of marine forms; the Barton beds, also full of marine forms, but telling a tale of a different sea; the Headon, Bembridge, and Hempstead series, with many repetitions of marine and fresh-water conditions, indicating long lapses of time. There is, too, the whole Miocene period, of which we have no trace in this district, but which we believe from continental evidence was of vast duration. Then, too, there followed periods of immense length, during which England underwent its latest glacial epoch; after that, the time during which the gravels were formed. While, therefore, we speak of these beds as almost the youngest of our series, they belong to periods of an incalculably remote past.

It is from the cliffs principally, and from the deep cuttings of the recently constructed railway from Bournemouth to Parkstone, that our knowledge is mainly derived. There are, in addition, the diggings carried on for commercial purposes. Great interest attaches to these somewhat monotonous-looking cliffs, as it is from them that has been unearthed the marvellously rich flora which I shall briefly describe further on. Let us commence by visiting the diggings near Wareham. We see that they are situated on a wild moorland with hillocks, under the high range of chalk downs, in a gap in which stand the massive ruins of Corfe Castle. Very bleak and barren the scenery looks in high winds and driving showers, and the latter are of unusually common occurrence, the clouds being caught and held by the high downs. The moorland stretches far to the sea and enwraps Poole Harbour, continuing as far as the eye can reach, beyond Bournemouth to the tower of the fine old abbey of Christchurch and to the New Forest, being here and there clothed with extensive pine plantations. But in fine weather it has a charm of its own and is especially lovely when the yellow furze and purple heather are in full bloom. Even the actual diggings themselves are most picturesque, especially those now abandoned, as there we find little deep blue lakes surrounded by many-coloured cliffs fifty feet in height, in which bright yellows, magentas, and crimsons predominate. I do not apply the word blue to the small lakes poetically, for they are of an intense blue, finer in colour than the famed blue of the waters of some of the Swiss lakes. The heath is, in some patches, of a magenta colour, where a crimson clay patch forms the soil. If we examine these cliffs and banks we find them composed of clays dark or white, or red and white mottled, of layers of coarse grey grit and of sands of every shade of red and yellow, white, and variegated. Often the sands have angular lumps of clay imbedded in them. The quarrying is mostly done in open pits, the clay being dug out perpendicularly with a long and narrow spade. Some of the deeper seams are mined, and a considerable depth is reached in Mr. Pike's workings, and at Branksea it is worked under the sea-level. These pipeclays are exported to all parts of the world wherever good pottery is made.

---

[1] Lecture in connection with the Loan Collection of Scientific Apparatus, given at the South Kensington Museum, December 2, 1876, by J. Starkie Gardner, F.G.S.

Overlying the pipeclays we find another series of deposits, which are not here quarried for use, but looked upon as refuse; but near Bournemouth they are dug into in many places for the brick earth contained in them. They are easily distinguished by the darker colour and more sandy nature of the clays. These drab clay basins are of smaller extent and are full of remains of decayed leaves, and have actual seams of coal in them, which is burnt by the villagers. We now cross Poole Harbour, at high tide a magnificent sheet of water, the distant hills, behind which the sun sets, giving it the appearance of an Italian lake, and glance at Branksea Island as we pass—the owner of which, however, will not allow us to land. In the sheltered bay of Studland we can see but little of the cliffs, as they are now mostly overgrown to the very beach. We are struck, however, by the coloured sands which forcibly remind those of us who are familiar with them of the still more brilliant hues of the sands at Alum Bay.

Being ferried across the inlet of Poole Harbour and walking along the beach towards Bournemouth, we find the coast for the first mile composed of hills of blown sand, beyond which the cliffs we have been viewing from a distance rapidly rise. These cliffs are themselves of rather monotonous appearance, being devoid of the brilliant colouring so conspicuous at Alum and Studland Bays, but they are crowned for the greater part of their length with pine woods. Their colour varies from buff to white and from white to slate colour. We notice apparently endless successions of clays, sands, and grits deposited at different angles and without any single bed being traceable for more than a few yards. The cliffs, preserving the same characters for a distance of four miles, extend to near Boscombe, where we notice a change in their composition. The clays are black and still more sandy, the upper parts of the cliffs are far less steep and seem composed of loose white sands and shingle with a thick capping of gravel.

At length still further east these beds disappear beneath the sea in consequence of the general dip of the strata. The sand beds which follow, where they cap the cliffs, are recognised from a great distance by their greater slope from the cliff shorewards, for they are so loosely composed that every wind blows the sand away in clouds and leaves the shingle to rattle down on to the beach. So loose is this material that that part of the coast line which had cliffs composed of this sand has now but an insignificant height; all the sand has been blown away by wind and wasted by rain, until the shingle has been left dropping lower and lower, and the stones which neither wind nor rain could affect, have come closer and closer together. This is the cause of the land connecting Hengistbury Head being much lower than any other in the neighbourhood. The shingly beds are ancient sea beaches, and the slope of them to the ancient sea can still be seen in places. So long have they been exposed that the flint pebbles in them are sometimes almost decomposed, the familiar white coating to the flints being an inch or more thick. This shingle, which is composed of rounded pebbles, that tell the tale of a long rolling on the old sea beach, is now the source of the pebbles on the present beach, and the round condition of the pebbles on the present beach on this part of the coast is not as on the shore further towards Poole, or as at Brighton, the result of present wave action, although the existing sea has undoubtedly reduced the pebbles in size. They cannot be confounded with the later angular river gravels which everywhere cover this area.

At the peninsula of Hengistbury Head, about six miles beyond Bournemouth, the cliffs again rise, being at first composed of black, chocolate-coloured, and white sands with pebbles, and farther on of green clayey sands containing nodules of large irregularly-shaped concretions of sandy, argillaceous ironstone disposed in layers, until lately worked for iron and shipped to the smelting furnaces of South Wales. Beyond Christchurch Harbour we have cliffs of white sand which, according to my views, close the series.

Inland the country has a barren appearance except in the plantations, and the scattered brick pits afford no additional information of use to us in our present researches. There is but little of interest to the tourist except on the very edges of the district where the archæologist will be interested in the Minsters of Christchurch, with its associated ruins, Wimborne, and the ruins of Corfe Castle.

No order of arrangement is at first apparent in these beds, but by going backwards and forwards over the ground attentively there is, it seems to me, a very well-marked and recognisable sequence. I will now tell you what I take to be this sequence. It has never been submitted to geologists before, and it is possible, as is often the case with new work, that there may be some objections raised to it.

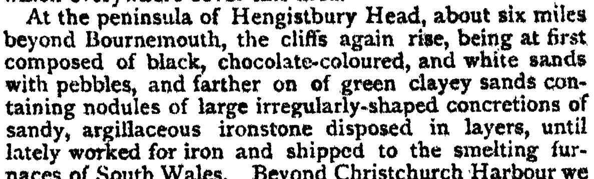


FIG. 1.

I would refer to the diagram (Fig. 1) where I have expressed my reading of this district. This lower fresh-water series is seen in the neighbourhood of Corfe and forms part of the cliffs at Studland. It is characterised by abundance of pipeclays, and has a thickness of 200 feet or more.

The middle freshwater series, also met with near Corfe

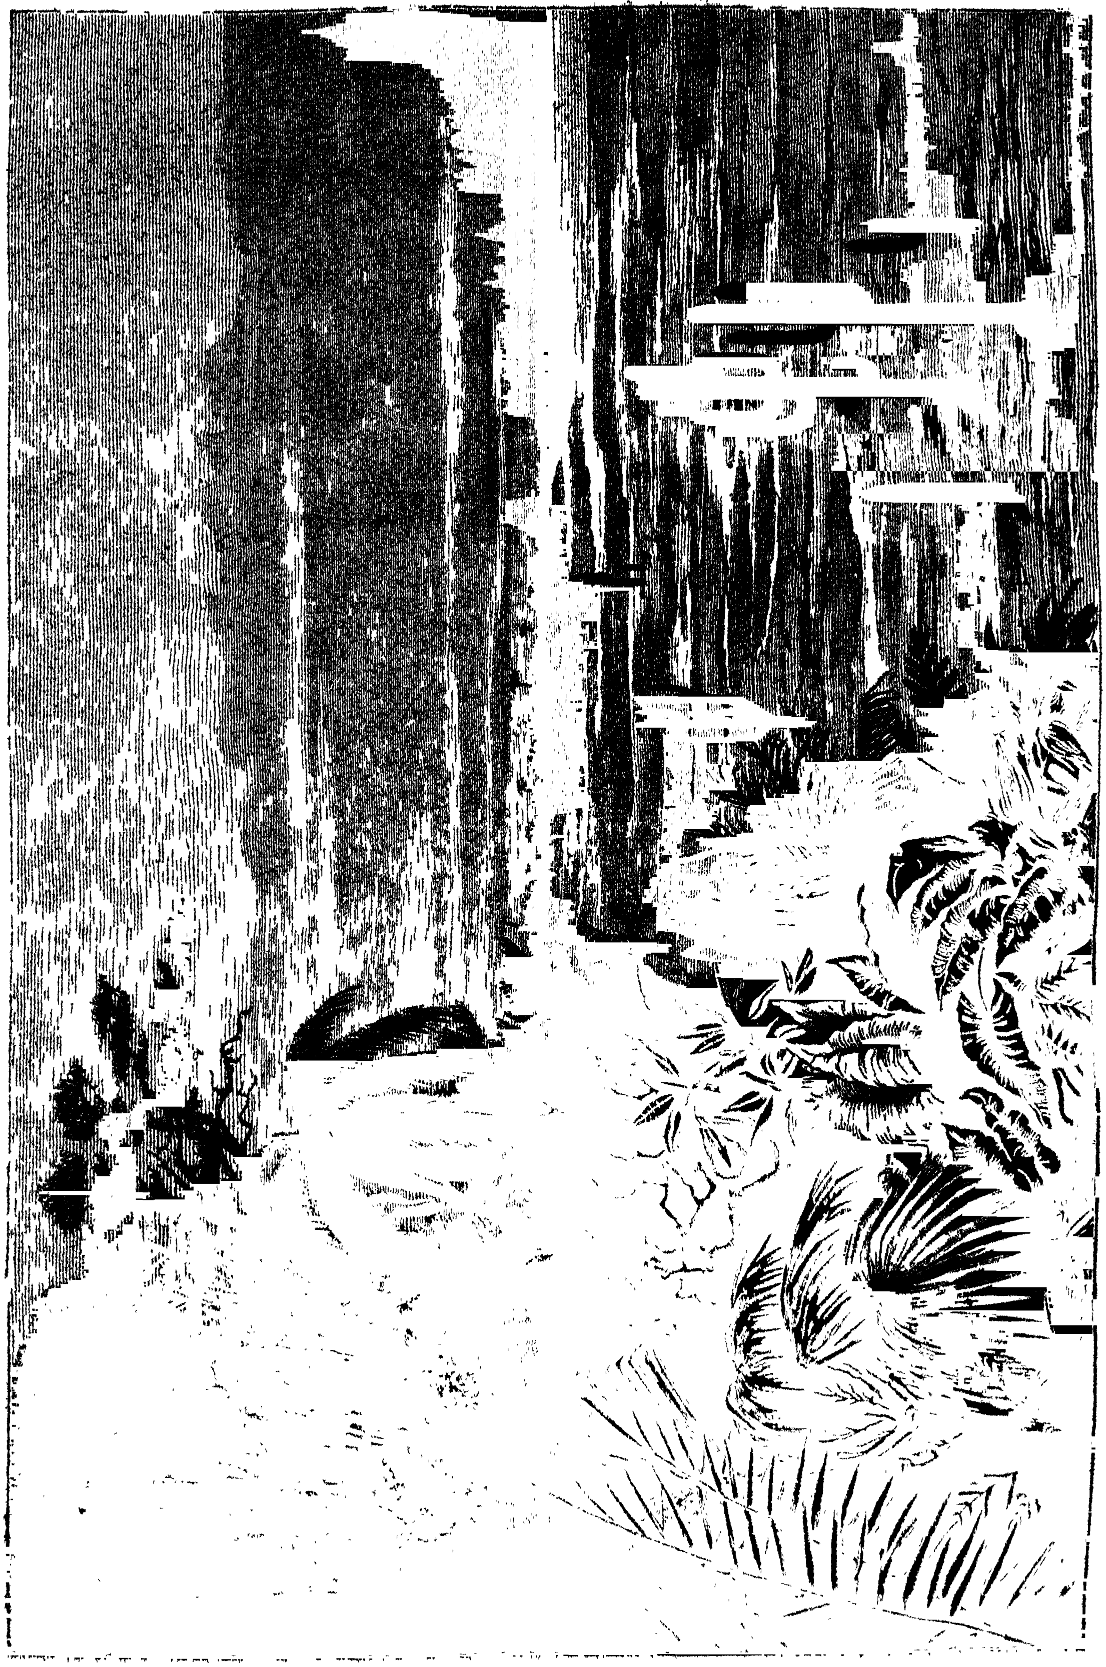

Fig. 2.—The Valley of the Bourne restored to represent the conditions which are supposed to have existed during the deposition of the Lower Bagshot Formation. From a drawing used in illustration of Mr. Gardner's Lecture.

and at Studland, forms the whole thickness of the cliffs between Poole Harbour and Bournemouth. We thus have a magnificent section four miles long and 100 feet in height. Branksea Island is also formed of this series. Their entire thickness cannot yet be accurately stated, but may be put down at some 300 feet. They are characterised by the fact that the clays contained in them are usually brick-earth.

The next series above is a marine series and is some 400 or 500 feet thick. The base beds are dark sands and clays, succeeded by pebble beds and sands, then more sandy clays with pebbles, and ending with a thick deposit of white sands. This marine portion of the series occupies the cliffs between Boscombe and High Cliff.

Plain as this order of deposition appears, we have collateral proof that this interpretation is right, for at Alum Bay there is a complete section of the whole of these beds although somewhat thinned out, upheaved vertically, that is, turned completely on end, so that we can examine them in detail in the space of a few hundred yards, like passing in review volumes on a book-shelf. We see in succession the lower pipe-clays, the brilliant sands, the darker clays, sands, pebble-beds, one after the other, so tilted up and so placed that those who know nothing of the depression and elevation of areas can with difficulty be brought to believe that they have all been deposited horizontally.

In giving you the history of the deposition of these beds, I shall have to speak of a sinking area, and before doing so let me remind you that in Lyell's "Geology," a book in everyone's hands, many instances are recorded, of sinking areas in historic times, from our knowledge of which we feel justified in supposing that there were sinking areas in geological times.

The thick pipeclays and quartzose grits which we find at the bottom of the series can without the slightest hesitation be referred to the result of the wearing away of granite rock, for wherever granite is worn away by water, there we find white clays and similar quartz grits. We need not go further than Cornwall to see still finer clays, which have been produced in quite recent times from granite by the agency of water. The beds of this district included in the Tertiaries, first laid down over the chalk, were those now called London clay (a marine deposit), and when the streams which brought down our Bagshot beds first spread out their deposits, they spread over the London clay, except, perhaps, in those places where they first cut away the London clay, so that some of these Bagshots were possibly laid down on the chalk. The water in this case came from the west, and as here we are nearer the hills, which were the source of the clay, we find the grits coarser and the clays thicker.

At Studland the grits are not so coarse, and at Alum Bay, a long way east, the sands are very fine, so that anyone knowing the district could tell which of these specimens came from either place.

Each clay-patch represents a small lake, first scooped by the running water out of the beds just previously deposited, and then filled in by sediment. The mode of action is this:—The weather disintegrates the exposed surfaces of the distant granite rocks, and the loosened particles are carried by rain into streamlets, which convey them on to the river. The river, tearing and tumbling along, grinds the rocks which have fallen into its bed into round boulders, until in flood times the water is white with finely-divided granite. This grit being hurried along by the rush, is spread far and wide over the valley whenever the stream bursts its banks, which mountain torrents very often do, while the finer particles are still held and carried on until a lake or pool is met with, where the speed is checked; these fine particles are then dropped, and the water becomes quite clear. This deposition of fine clay goes on for ages, until the lake becomes filled up, the water gets diverted into another channel, and what was a lake becomes dry land; the river at the next flood spreads over the valley, covers in common with the surrounding ground what was the lake again and again with thick grits. Such is the origin of the large basins containing the clays which serve now to make your pipes and your crockery. You have only to recognise that the valley in which this takes place was slowly sinking, and there is no limit to the thickness of sands and clays which might be thrown down on any one spot, and in this way can be explained the sudden changes from grit to clay, which would else be a puzzle to us. The size of these old lakes is very well seen now wherever a clay basin has been quarried away, for the clay is quarried away for use whilst the sand is left. Some of them are represented by the beautiful blue pools I told you about, and are seen, therefore, to have been about one-quarter to one-third of a mile round, whilst their depths have varied from 30 to 60 feet. Mr. Lawrence Pike informs me that other clay basins are of larger extent, being ¾ of a mile in diameter. Their greatest length is in the direction of the valley. These clays extend under the surface, eastward, for they are worked at Branksea under the sea-level, at Parkstone, and near Bourne. At Alum Bay they are tilted up, and are full of beautiful fossil leaves.

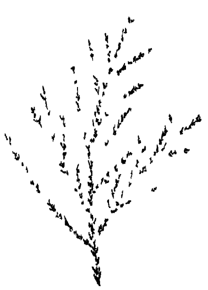
This next series of beds above, which I have told you are of a different character, mark a great change in the conditions of the land. The clay patches are of smaller extent, being the filling in of mere ponds or puddles, which acted on a smaller scale, as the lakes of which we have just spoken. The change indicated by these beds is one from the valley in which the previous contained beds were deposited, to a broad low-lying tract in proximity to the sea. We infer that we can trace how this tract became gradually lowered and lowered down to the sea-level.

The belief in the gradual lowering of the land in this area is borne out by the fact that in the cliffs near Poole, which are slightly lower in position than those farther east, we get only leaves of evergreens and forest trees, whilst as we work our way east so as to meet with beds on a higher level or, which is the same thing, of more recent age, we get a mixture of ferns and other plants, which require much moisture, whilst farther east still we get assemblages of plants that could only have lived in absolute swamps.

Low as the land appears to have become we have no evidence whatever, throughout the whole thickness of this part of the series, amounting to 300 feet at least, with an exception which I will tell you about directly, that it was low enough to be inundated by the sea, as the few shells that have been found are of fresh-water kinds. The exception alluded to is the occurrence of logs of wood bored by the ship-worm or teredo. All the ship-worms generally known to us live only in salt water, and are so delicately organised that the slightest mixture of fresh water instantly kills them. This isolated fact for some time presented a grave difficulty, but happening to read Mr. Gwyn Jeffreys' interesting account of the habits of this creature, I not only found that he relates the occurrence of similarly bored wood 300 miles up the River Gambia, but distinctly states that there is a species which lives in fresh water. Therefore this supposed marine indication may be on his authority removed, and, supposing this theory should be verified and universally accepted, we may safely infer that these middle beds are of fresh-water origin.

We now come to the third series of beds. A still continued sinking of the area brought this swampy condition so low that the sea was no longer kept out, but, bursting through, formed great salt-water lagoons teeming with life; for we suddenly find crowds of marine forms imbedded in what was formerly black mud, such as we might find now in the existing Poole Harbour here.

In this series of marine beds we have at the bottom lagoon beds, as I call them, which may represent a similar state of things to what we see at Christchurch, or Poole, or Weymouth, or any place where we have mud banks left dry or even shallow, between each returning tide. We still find here leaves of trees, many of them doubtless overhanging the lagoons, which have so slowly decayed, that they are overgrown with zoophytes; crowds of oysters are met with; we find the remains of shore-crabs, which from our knowledge of existing species, we infer, overran the muddy shore; the callianassa, a prawn-like creature, which bored through the mud; limpets, arcas, corbulas, and many other shell-bearing molluscs, passing their lives, dying, and becoming buried in the sediments of the sheltered lagoons. This lagoon condition went on until the gradual sinking has permitted the ever-encroaching surf to break over the lagoon barrier, to rush in, and in time overwhelm them with rolled shingle and sea-sand. We still trace the lagoon condition for a mile or so east, where it is represented by cigar-ash coloured sands, impregnated with salt, and coloured with this dark tint of carbonaceous matter. These sands contain very perfect remains of branches of a coniferous tree resembling the genus Dacridium and large pieces of cactus. It should be mentioned that this is the earliest cactus known, and that the spines are found to be still flexible. The sands are in other places crowded with fruits something like those met with at Sheppey. Unfortunately the salt contained in them effloresces and splits all these specimens into fragments.



BRANCH OF CONIFER

Fig. 3—*Taxodium.*

I may just tell you that at Hengistbury Head we have deeper sea deposits, with sharks' teeth and bones. At Highcliff, Barton, we have relics of a sea swarming with life, myriads of fossil shells may be collected on the cliffs, whilst still further on at Hordwell, we have beds showing that the land arose again, affording suitable conditions for the growth of luxuriant palms, and was the haunt of the alligator, turtle, and other reptiles which are now confined to tropical countries.

Fig. 2 is a view of the Valley of the Bourne at the time referred to above; a description will be given in the next article. (*To be continued.*)

GEOGRAPHICAL CURIOSITIES

DURING the meeting of the International Geographical Congress at Paris in 1875, the National Library opened an exhibition supplementary to that which was held in the Tuileries. Although very rich in documents and modern geographical works, the great national institution did not wish to show simply a duplicate of the collections exhibited at the Tuileries, and it therefore brought out only ancient and rare objects which the rules of the establishment wisely forbid to leave the building. Thus it showed to the public neither its great topographical maps, such as those of Cassini, van der Maelen, &c., nor its recent atlases, its numerous geological maps, its hydrographic charts of the French, English, and other Admiralty Departments. But, thanks to M. Leopold Delisle, Administrator-General of the National Library, and to M. E. Cortambert, Librarian of the Section of Maps and Plans, there was exhibited in the magnificent Mazarin Gallery a collection unique of its kind, and to which the Departments of Printed Books, Manuscripts, and Engravings contributed. The objects exhibited belonged generally to Group IV., devoted to Historical Geography and the History of Geography, and comprised, besides ancient and modern works and MSS. treating of geography and its history, ancient maps and globes, instruments used by ancient geographers, astrolabes, sundials, &c.

The success of the exhibition in the Mazarin Gallery inspired the Administration of the Library with the happy idea of transforming this temporary exhibition into a permanent institution. This has been established in the ground-floor of what is known as the "Salle des Globes," and in the two rooms which look out upon the great court of the Rue Richelieu, has been recently opened to the public who are admitted on Tuesdays from 10 to 4.

Although the limited space at disposal in these apartments has not permitted the transference of all the objects exhibited in the Mazarin Gallery, and although the Departments of Manuscripts and Printed Books have kept possession of some of the valuable documents lent on the occasion of the Geographical Congress, the exhibition is nevertheless of the greatest interest on account of the rarity of the objects which it contains. Space forbids us to give a complete list of the many objects exhibited, though we are able, through the courtesy of the editor of *La Nature*, to give illustrations and descriptions of a few of the curiosities. There are nearly 500 objects altogether, and those who desire a complete descriptive catalogue of them should procure No. 178 of the French journal just referred to.

On entering the first room of the exhibition the visitor is at once struck with the large dimensions of the two great globes of Coronelli, made, in 1683, by order of the Cardinal D'Estrees, who presented them to King Louis XIV. One of the most curious objects shown in this room is a map of the world, probably of the ninth or tenth century. It is a copy of one which appeared in a Commentary on the Apocalypse written by Beatus, a benedictine of the monastery of Valcovado in Leon, who lived in the eighth century. The original of which the one exhibited (Fig. 1) is a copy, belongs to the library of Turin. It shows strikingly the wonderful notions which these old monks had of the universe, and especially of the earth in which they dreamed their uneventful lives away. Four winds, represented by the grotesque figures seated upon the skin or leathern bottles, and holding shells in their mouths, indicate not the four cardinal points, but the collateral points, where the sun rises and sets at the summer and winter solstices. The orientation of the map, as was for long the custom in the middle ages, places the east at the top, the west below, the north on the left, and the south on the right. A circular ocean, the old river Oceanos of Homer, surrounds the world. If we examine the interior of this strange *mappemonde*, Europe will be seen on the left, Africa on the right, and Asia at the top. The Mediterranean is represented by a very regular parallelogram, extending from east to west. A not less regular branch of this sea occupies the place of the Archipelago, the Black Sea and the Sea of Azov, and bounds Europe on the east, the north-east point of the continent being indicated by the words *Hic Caput Europe* (Europæ). Islands uniformly square are spread over the Mediterranean; we may recognise under strange names, Corcyra, Cyprus, Samos, Sicily, Corsica; the name *Tassis*, which may also be noticed, designates, no doubt, the City of Tarsus, which the author evidently regards as an island.

In the surrounding ocean appear other islands not less fantastical. On the east the island of Crisa and Algure (for Argire), in allusion to the region of gold and silver of the ancients, in trans-Gangetic India; on the north-east the Island of Tulé, which recalls the famous Thulé; Britannia; then the Island of Scotia, which, however, is not Scotland, as many might be apt to think, but the original home of the Scots, Ireland; for it was not till about the twelfth century that the name was fairly transferred to North Britain.

The orography of Europe is shown, partly in enormous cones, partly in elongated masses, five principal chains, of which only one is named, the Mountains of Gaul (*Montes Galliarum*), without doubt, the Pyrenees. The hydrography is wretchedly meagre. The largest river is correctly set down as the Danube (Danubu), but what a curious course is given to it! The second in extent is the Tagus, under the name of *Tavus*, which in utter contempt of geography, discharges itself into the Mediterranean. What considerable river is that which flows towards the east under the name of *Eusis*, a name still applied in Asia to a large river situated almost opposite to this one? Perhaps it may be meant for the Pontus Euxinus itself, the Black Sea; for to mistake a sea for a river was not an uncommon thing with these old geographers.

The political geography is of a higher kind than the physical geography. To speak only of Gaul we find mention made of Aquitaine, Toulouse, Gallia Lugdunensis, and Gallia Belgia; we also find *Francia*, which, however, does not stand for France but for Franconia.

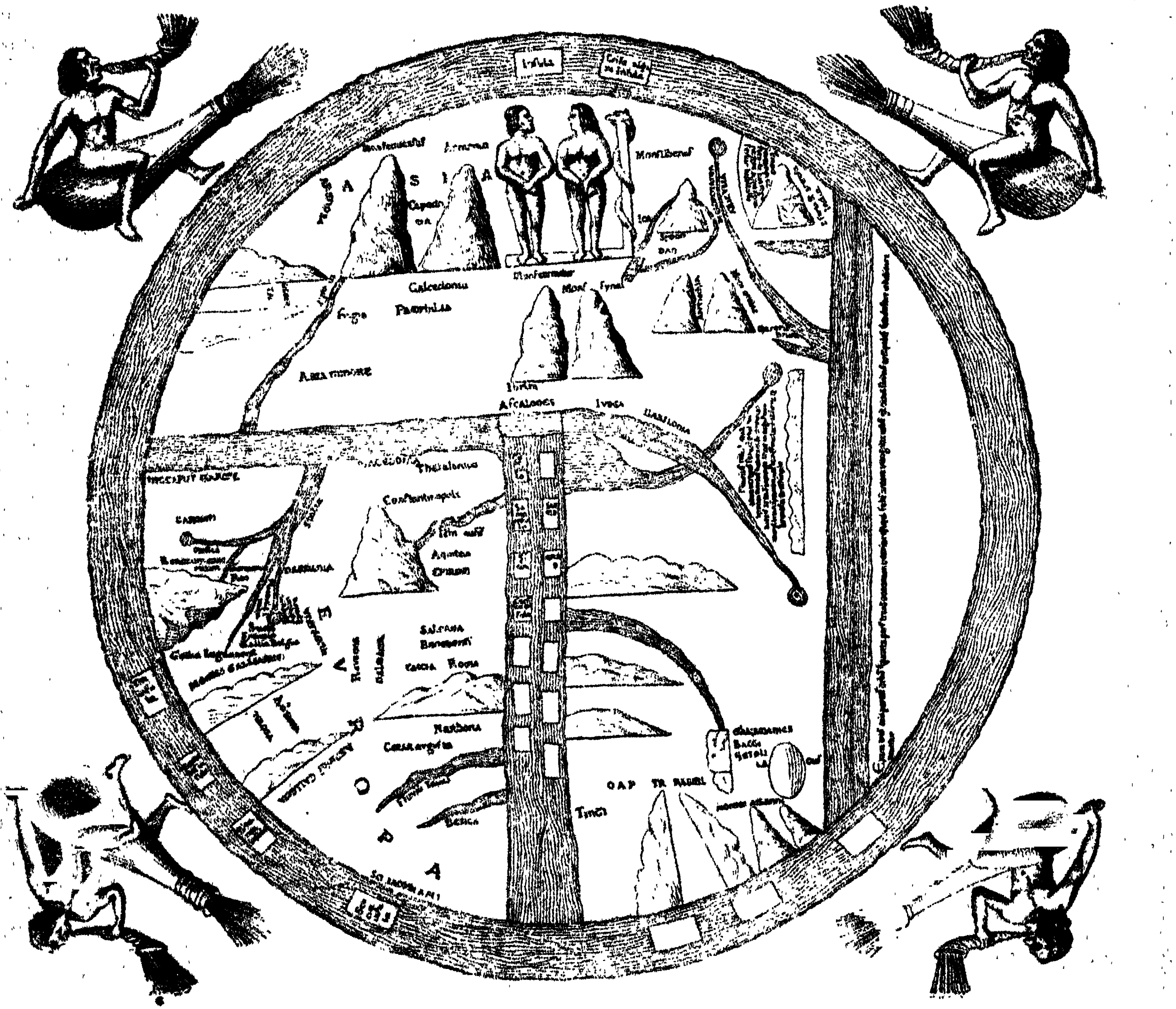


Fig. 1.—Map of the world contained in Beatus's Commentary on the Apocalypse (10th c.).

In Asia, on the spot, no doubt, where Paradise was supposed to have been placed, appear Adam and Eve, in a grotesque position, and near them the serpent, who, however, has nothing tempting about him. Ten conical mountains surround this curious scene, without names except Libanus, the Caucasus, Carmel, and Sinai. Only three rivers flow in this vast space: first the Jordan, which encompasses Mount Lebanon in a very strange way; the Euphrates, which, though it bears no name, may be divined by the name Mesopotamia written on its banks; and then the Eusis, that mysterious Eusis to which we referred above.

The countries and the towns are more abundantly treated, though scattered pretty much at hazard. Jerusalem holds the first place, under the abbreviation, Ihrlm; Judea, Ascalon, Sidon, Antioch, Asia Minor, Phrygia, Mesopotamia, &c., are represented in situations more or less inexact.

In Africa, what strikes one at first is the Nile, the enormous Nile, divided near its sources into two branches, each issuing from a lake; it falls into the sea by a mouth larger than that of the Mediterranean itself. A note inserted between its sources tells of the gold which is mixed with the sand of the river, a vast lake which it traverses, and the sandy deserts of Ethiopia, through which it flows. The only other river seen in Africa is one without a name, which descends from the country of the Garamantes and falls into the Mediterranean; it is probably the Bagradas—the Medjerda of the present day. The mountains of Africa are but poorly shown. After Mount Atlas (*Montes Atlanni*), which is neither in its place nor very markedly brought out, there may be noticed three mountains which abut in the Mediterranean, and two steep and sharp-pointed mountains designated by the scarcely legible words, *duo Alpes Contra Arasibi;* this should perhaps be read *Contraria sibi, i.e.*, two mountains opposite each other, forming, as it were, two walls between which is a narrow passage. But where exactly are they?

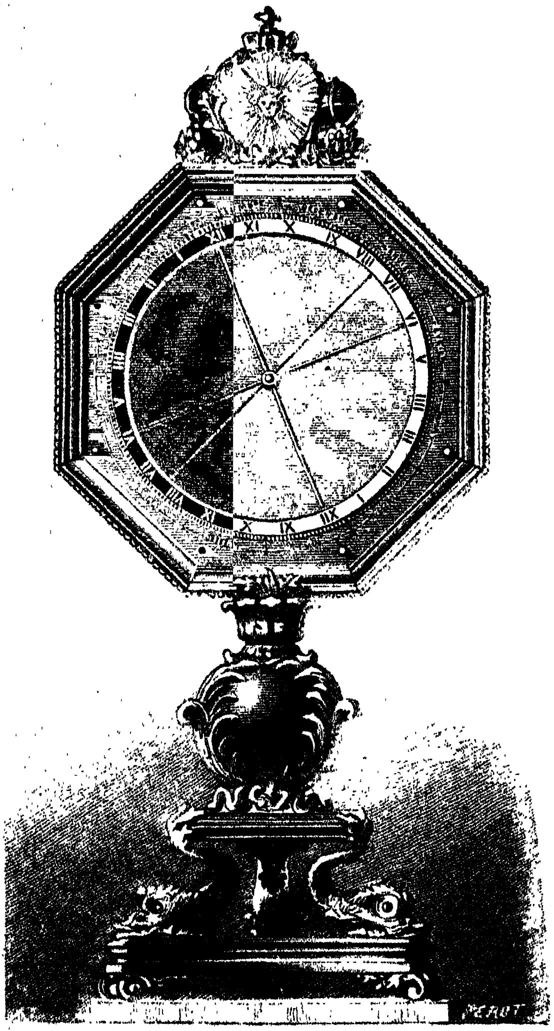

FIG. 2.—Copper cosmographic apparatus.

A note inserted in the south of the map tells us that, independently of the three points of the known world, there is beyond the ocean a fourth part which is unknown to us on account of the heat of the sun, and on the confines of which, it is fabled, adds the author, that there are Antipodes.[1]

A reproduction of this map belonging to the 11th century shows a marked progress on that which we have just described.

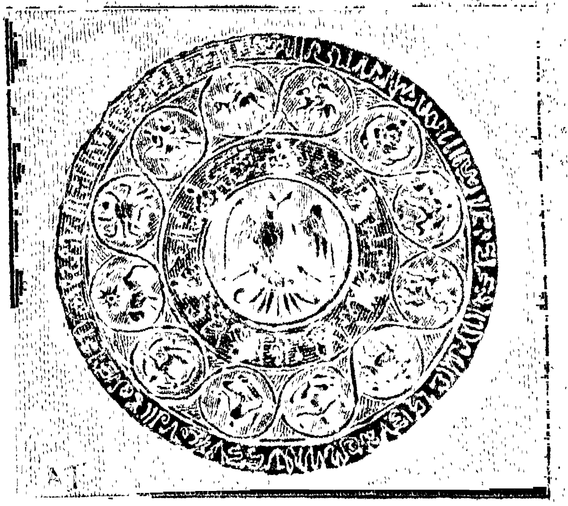

FIG. 3.—Arab zodiac (one-fifth size of original).

The room in which this map is exhibited contains many equally curious objects, some of them of great rarity and value. Among these we may mention a copper cosmographic apparatus (Fig. 2) by Thuret, of date 1725. On one face are represented the northern constellations and the signs of the zodiac, as well as the correspondence of

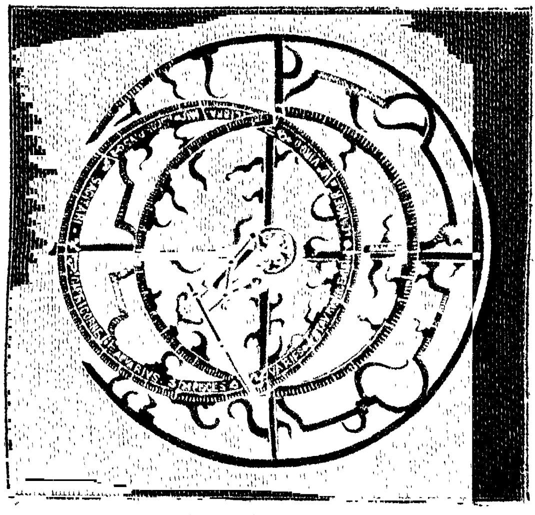

FIG. 4.—French astrolabe (one-fifth size of original).

MARTIN BEHAIM'S MAP OF THE WORLD.
1492.

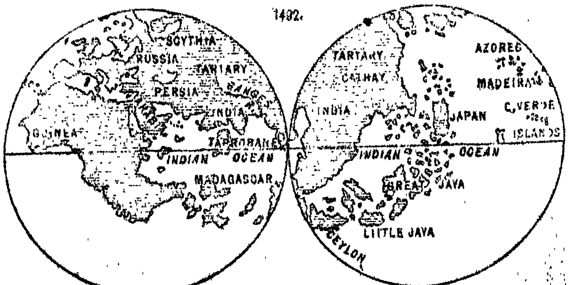

FIG. 5.—Martin Behaim's map of the world.

---

[1] For the above details we are mainly indebted to an article recently published by M. E. Cortambert.

these signs with hours and days; on the other side is shown the movement of the planets around the sun. It is worked by means of a clockwork mechanism in the interior, and is made to indicate the days, months, and years. In other rooms are shown the curious Arab zodiac represented in Fig. 3, and a French astrolabe (Fig. 4) made by François Chassignet, and of date Rome, 1622. Another interesting object is a facsimile map of the world, painted on parchment by order of Henri II. (1547–1559). Some critics, among others M. D'Anezac, date it as far back as the time of François I. (1515–47). In Fig. 6 we have reproduced a portion of South America after this curious document.

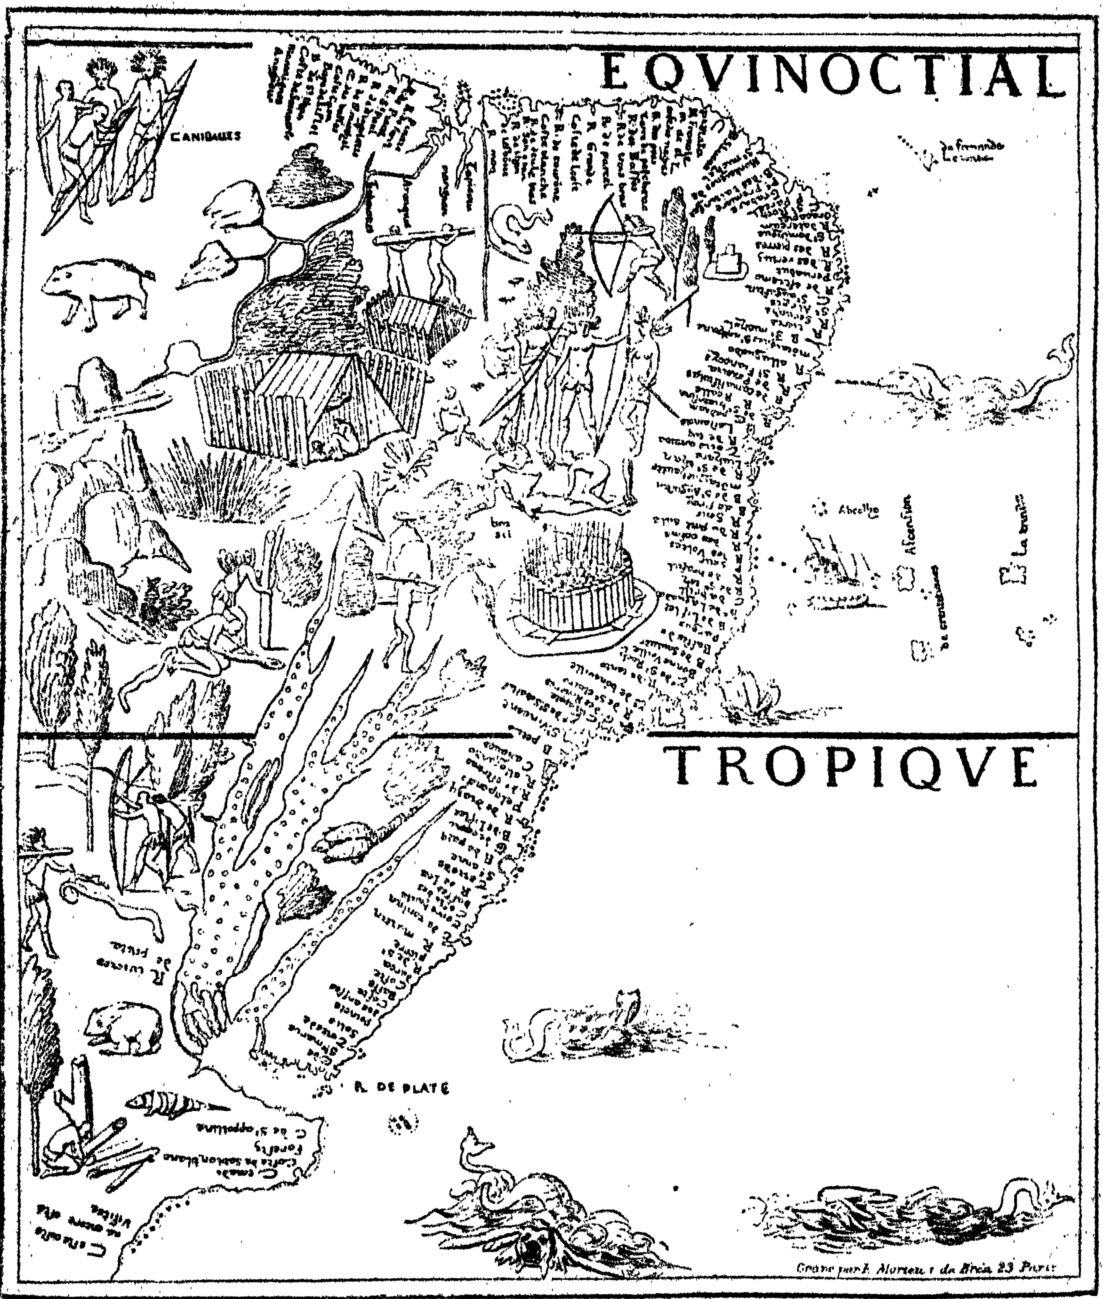

FIG. 6.—North-east region of South America (16th c.).

Among other objects is a facsimile of the well-known globe of Martin Behaim, of date 1492, the original of which is at Nuremberg. This globe is extremely curious, specially on account of the lacuna in the region where America should be, that continent not having been discovered when the globe was made. An idea of the contents of this globe may be obtained from the illustration, Fig. 5. There is also the only known copy of the celebrated map of the world of Sebastian Cabot, of date 1544. A valuable legend in Latin and Spanish informs us, among other things, that John and Sebastian Cabot landed on the new continent in 1494.

Such are a few of the objects exhibited in this extremely interesting and instructive collection. No doubt many of our readers will be glad to know of its existence, and hose who take an interest in the progress of geography will doubtless think with us that such an exhibition adds one more to the many attractions of Paris; now that the Loan Collection is closed, nothing at all approaching it exists in London.

TEMPERATURES AND OCEAN CURRENTS IN THE SOUTH PACIFIC

IN the *Annalen der Hydrographie und maritimen Meteorologie* (Jahrg. iv., 1876, Heft 6, p. 219), Herr von Schleinitz, a member of the recent expedition in the German corvette *Gazelle*, states his views on ocean temperatures and currents; these are somewhat different from hose expressed by Sir C. Wyville Thomson (Proc. Roy. Soc., vol. xxiv.), which are based on the data obtained during the *Challenger* expedition. The *Gazelle*, after eaving Auckland (New Zealand), pursued a course lmost due north as far as the Fiji Islands; thence he proceeded to the Samoan Islands, situated at a hort distance north-east of Fiji. After a brief excursion o the Tonga group and back, the *Gazelle* (from long. 72° 18′·5 W., and lat. 14° 28′·1 S.) sailed some 2,500 nautical miles in a south-south-east direction (to long. 41° 11′·4 W., and lat. 45° 33′·6 S.), after which she took a due easterly, and later on, a south-easterly course, to Magellan's Straits (long. 80° 30′·3 W., lat. 51° 41′·6 S.). The observations of temperature on the long cruise beween the Samoan Islands and the Magellan's Straits are of special interest, as the course taken by the *Gazelle* ies to the south of that pursued by the *Challenger*.

On the first part of the course described, which has a direction nearly coinciding with the meridian, eight series of observations of temperature were made. The bottom profile of this part shows a peculiar absence of elevations, which is all the more remarkable when compared with any similar profile of the same length in the Atlantic.

The conclusion arrived at by Herr von Schleinitz, and based on the results of his observations is, that in the Pacific the arctic deep-sea current crosses the equator in a southerly direction and meets the antarctic current only between lat. 30° and 36° S. This is just the reverse of what takes place in the Atlantic, as it seems highly probable from the observations of both the *Challenger* and he *Gazelle* expeditions, that in the Atlantic the antarctic deep-sea current passes the equator, running northward of he same to a considerable distance.

Herr von Schleinitz concludes from these latter obervations, that if the antarctic deep current enters the North Atlantic, even as a current of limited breadth, it must nevertheless carry enormous quantities of water from he South Atlantic to the North Atlantic, as it is certain hat the current has a depth of more than 1,000 fathoms on he average. He then asks the question, What becomes of this mass of water? There is no strong surface current n existence which carries it back to the South Atlantic; even the current caused by the south-east trade winds uns more towards the Gulf Stream than towards the Brailian coast current. There seems only one hypothesis possible, viz., that a great part of the water flows through he Arctic Sea and Behring's Strait into the North Pacific, and that may be the cause of the preponderance of the arctic current of this ocean over its antarctic one.

The natural conclusion drawn from this is that the South Pacific, in order to complete the whole circle, gives a great part of its waters to the South Atlantic, and as a proof of this it might be pointed out that the ice limit does not approach the equator so much anywhere as it does in the South Atlantic.

The following facts may also be mentioned as in favour of the hypothesis of a certain regular circulation taking place in the manner described. A comparison of the air-sotherms as well as the sea-isotherms both of the Atlantic and Pacific Oceans shows that (1) the South Atlantic is colder than the North Atlantic; (2) the North Atlantic is warmer than the North Pacific; (3) the South Pacific is warmer than the South Atlantic.

The higher temperature of the North Atlantic Ocean has hitherto been generally explained by the influence of the Gulf Stream. But a similar current exists in the North Pacific, and yet this is colder. There is no doubt that the Gulf Stream has a warming effect on some European coasts, but it is very probable that considering its comparatively small breadth of about 100 nautical miles, and shallow depth of only 100 fathoms, the stream is far too insignificant to be able to exercise a perceptible influence upon the climate of the whole North Atlantic and of the coasts surrounding this ocean.

On the other hand it does not seem to have been sufficiently appreciated hitherto, that a very large part of the North Atlantic is filled by water, which has crossed the equator, even if at a considerable depth. However trifling the rise in the temperature of this water, as caused by the passage over the equator, may be, when compared to the general temperature of the South Atlantic, it is nevertheless a fact that there is an important amount of heat, which the South Atlantic loses and the North Atlantic gains, on account of the very large extension of the current. Nor can it be objected with regard to this, that the mean temperature of that mass of water is probably below the mean temperature of air in the North Atlantic, because there is no question of absolute heat, but only of difference of temperatures between the North and South Atlantic.

The excess of water in the North Atlantic, which is not carried back into the South Atlantic by the surface-currents, and which passes through the Arctic Ocean (where it loses the heat it possessed) into the North Pacific, causes a decrease of temperature in the latter, and, proceeding southward, *i.e.*, again crossing the equator and thus absorbing heat, produces an increase of temperature in the South Pacific. Finally, the South Pacific gives back to the South Atlantic a part of that water at a very low temperature, which originally flowed from the latter into the North Atlantic perceptibly heated, on account of its passage through the tropics.

This circulation, however, is not to be understood as if the lowest strata of all the oceans took part in it; on the contrary, there are doubtless only single currents in the lower strata which follow it, while others may flow in an opposite direction. Further observations will throw light on these hypotheses; those made up to the present are yet insufficient and at times even contradictory. At the same time it must not be overlooked that a constant exchange of water between the lower and upper strata, *i.e.*, currents flowing in a vertical direction, are proved to exist beyond doubt, particularly in certain zones.

In conclusion Herr von Schleinitz considers the oceanic system of currents to be evidently a very complicated and at present obscure one, upon which the observations made on board the *Challenger* and the *Gazelle* throw but a very faint light.

The second part of the course pursued by the *Gazelle*, as described above, did not differ sufficiently in latitude, and therefore could not furnish any data which would be useful or decisive on the subject in question. However, the observations which were made give results in complete accordance with the hypothesis referred to above.

ON THE MEANS OF PROTECTION IN FLOWERS AGAINST UNWELCOME VISITORS

THE phenomena relating to this subject, which have important bearings on the doctrine of selection, have recently been discussed by M. Kerner in an interesting monograph communicated to the *Festschrift* published on occasion of the twenty-fifth anniversary of the Zoologico-Botanical Society in Vienna. The following is a brief outline of this paper:—

M. Kerner, first of all, thinks it unwarrantable to divide the characters found in plants into *physiological*, which bring their possessors a certain advantage, and *morphological*, which are of no advantage. While, no doubt, profitless and even disadvantageous formations occur in plants, it is yet certain that such individuals are soon extinguished and suppressed by others which bear advantageous characters. Most of the so-called morphological characters have rather a certain biological significance, and it is only from the lack of observations regarding them that the material for their comprehension is so defective.

Hitherto study has mostly been directed to the relations between the forms of flowers and those of the animals visiting them. M. Kerner gives an account of those manifold forms hitherto regarded as only of morphological significance, but the use of which is to guard flowers against uninvited guests and against all injurious influence, and attacks to which they may be exposed; these forms therefore are of essential biological value.

How numerous are these enemies and uninvited guests will appear from the following brief sketch:—First, there are the large grazing animals, such as the ruminants, solipedia, &c. Then there are snails, especially the voracious Helicidæ, which, indeed, are seldom found in the flowers, not because they despise them, but because they are kept from them by a group of stiff bristles and prickles underneath the flowers. The same holds for soft insects, especially many larvæ of caterpillars. The wingless aphides are, specially among soft insects, to be noted as unwelcome guests of flowers. They are found extremely seldom in flowers, being warded off by suitable means, but if they are carried into the flower they immediately force their proboscis into the sappy tissue. The insects with a firm chitinous skeleton, again, easily pass over the bristles and prickles; only their posterior feelers are sensitive to contact with sharp points. Among animals of this class those are injurious to flowers which, in consequence of their too small size do not, in passing through to the nectar at the bottom of the flower, brush against either the anthers or the stigma. They take away the nectar without effecting fertilisation. But even when the chitinous insects are of the proper size they are unwelcome to flowers if they are wingless, for in that case they are a comparatively long time in reaching the flower of another individual of the same species, and the pollen with which they are laden is exposed to so many hazards, that fertilisation by these insects is extremely improbable.

Now the means of protection against access of these numerous animals are very various, as we shall presently see.

We may first notice the protection afforded by the leaves, which produce the building materials of the flowers and are necessary to their growth. They afford protection through certain alkaloids and other compounds contained in the cell-sap, and also through a hard leather-like consistence and thorny processes by which a portion of the leaves are protected from injury by grazing animals.

The means of protection in the flowers consist, first of all, in the production of matters which are repugnant to some animals; such are alcohols, resins, and etheric oils, to which a number of the unwelcome guests have such a dislike that they will rather endure the sharpest hunger than eat these plants.

A second kind of protection consists in prevention of approach to the flowers by isolation of these with water, as is the case in the Bromeliaceæ. Generally the foliage leaves have funnel-like forms in which the atmospheric precipitates, rain and dew collect and so form an insurmountable barrier to the passage of creeping, wingless insects, while the access of the flying insects which affect fertilisation is not prevented. The water-plants are also defended against unwelcome guests which might otherwise creep to them; and it is very remarkable that in water plants with projecting flowers, other means of protection against creeping animals are wanting; they are only developed when the isolating layer of water, from some cause or other, disappears. Very instructive in this relation is the behaviour of *Polygonum amphibium*. To the flowers of the plants growing in water, creeping insects cannot come, the flowers being surrounded with water. When, however, the water has run off and the plant is on dry ground, there develop on the leaves and stalks gland-hairs, which secrete a sticky matter, rendering the flower-bearing axis all smeary, so that access is equally forbidden to the creeping insects. If, now, a plant of Polygonum bearing these gland-hairs be put in the water again, the trichome-tufts with their sticky material disappear, and the surface appears once more smooth and even.

Such a formation of sticky matters is developed in very many plants as a sure protection against unwelcome visitants. These sticky matters appear on the most different parts of plants, under the flower, and ward off especially creeping, but also unwelcome flying animals from the flowers. The variety of the glandular forms yielding sticky matter is very great, and their occurrence is very widespread.

While these sticky matters are effective against creeping animals which have a pretty firm chitinous coat, and especially against ants, they are ineffective against the soft creeping animals, *e.g.*, the snails, which secrete slime on the sticky parts of the plants, enabling them to pass over these. Against such enemies the plants are armed with the most various thorns, prickles, and sharp teeth, which mostly have their points directed downwards, but may have the most diverse positions and forms. Quite peculiarly interesting are those prickles and needles, which serve the purpose not so much of keeping off unwelcome visitants as of showing to the insects which visit the flowers the right way for effecting fertilisation; whereas if the same insects visited the plants and removed the nectar by another way, fertilisation would not be accomplished.

The means of protection thus far described are all on the path which the unwelcome guest must traverse if he would reach the flower. There are other means of defence, however, within the flower itself. These, indeed, cannot be regarded as absolute, for they may be overcome by unwelcome visitors. They consist of hair-like formations, which are united in large numbers, into grating-like groups, rendering access impossible to one animal, while to another, which is furnished with a longer, thin proboscis, or can drive with greater force against the grating, they yield the desired food. These soft hair formations, which have the most various modifications towards the end in question, also often serve to point the way by which welcome visitors may reach the nectar.

Where all the formations that have been mentioned are wanting, protection is still afforded by bends, enlargements, and collocations of particular parts of plants, which are so diverse that it is difficult to indicate them cursorily. In general they may be divided into two groups, one of which comprises those formations by which the nectar is completely covered, whereas in the other the entrance is merely narrowed so that an opening remains by which the animals may introduce their sucking organs. The most different parts of the flower share in these formations, producing a very great variety of forms.

A last means of protection of flowers is represented in those numerous cases in which the flowers open only in the evening, and thereby are guarded against the visit of insects which swarm during the day. Further, there is the diversion of injurious insects, due to the fact of the nectaries being sometimes situated in other parts of the plants, and mostly in the foliage leaves, so that creeping insects satisfy here their need of food, and do not trouble themselves about reaching the flowers higher up, and thus these remain protected from their visits.

"From the foregoing obervations," says M. Kerner, "it will sufficiently appear that the relations of plant-form to that of animals living at the expense of plants are far more manifold than has hitherto been supposed, and that especially numerous formations in foliage-leaves and stem are so far of biological significance that by them protection is afforded to the flowers against the prejudicial visits of certain animals. Where the attacking animals are absent this defence is also, naturally, useless, and therefore all these formations are properly to be regarded as means of protection only for those plant-stocks which occur in their original region—in the region where the species to which they belong has arisen. In another place they are perhaps not means of defence; indeed they may even be of disadvantage, or their formation there is at least something superfluous, not in the economy of the plant, and as a matter of course, these disadvantageous, because not economically organised plants, when they come under conditions which are not in harmony with their form, are driven out of the field by competitors that are more advantageously organised.

"If, for example, a plant species comes, in course of its migrations, into a region in which it is exposed to other attacks, or if the external relations in the place where the species arose (and with which it was formerly in agreement) are altered, it may become more and more rare, and gradually quite die out. Among these changes of external relations, however, are to be understood not merely changes of climate; a not less important part is played by the changes which occur in the animal world in a particular region. Apart altogether from changes in the extent of distribution of animals, the animals vary as well as the plants, and individual varieties, which occur with new characters that are advantageous relatively to given external conditions, may become the starting point of new species. What is of advantage, however, to the animals which attack the plants, constitutes, as a rule, a disadvantage for the attacked plant, and it is therefore not only possible, but in course of time it has actually often happened that in consequence of the multiplication of an advantageously organised animal form in a certain region, some plants in this same region having their flowering function destroyed, and their formation of seeds hindered, have disappeared gradually from the scene.

"While, on the one hand, the dying out of certain species with altered external relations, is at once explained by changes in the attacks of animals, the same relations, on the other hand, afford an explanation of the phenomenon, that under similar external conditions, plant species, which, with reference to other characters, are classed under the most different genera and families, do yet in certain formations agree with each other. Only the advantageous forms can maintain themselves, and only those individual varieties which appear with characters that are advantageous with reference to the conditions presented by the locality and position become the starting-points of new species. Since, however, the creation of new species in this way may occur in the most different plant-families, it is explicable that we find, *e.g.*, in one floral region, very many species of the most different stocks guarded with prickles, in another floral region such species furnished pre-eminently with flowers very rich in nectar, and that often even the character of the whole vegetation is determined by the preponderance of plants with like formations. Owing to the fact that the variety of the means of protection, as well as of the means of attraction is very great, and that through formations of the most different kind the same result can be reached, this conformity is again, of course, greatly limited. Indeed, precisely by this circumstance that, against the same prejudicial attacks, very different formations may serve as equally good means of defence, is the phenomenon explained that frequently several species of a family occur beside one another, without entering into competition in this relation, because the species, each after its own fashion, possess equal advantages."

THE ACTION OF THE WINDS IN DETERMINING THE FORM OF THE EARTH[1]

In view of the most recent discoveries in the region of physics, especially with regard to the nature and properties of forces, it became necessary *eo ipso* for dynamical geology to give up as unsatisfactory the division of geological forces into "igneous" and "aqueous," and to substitute a division of them into "primary" and "secondary"; of which the former explain all the motions which we observe on and in the earth, according to their origin and nature; while the others—one might call them "agencies" to distinguish them from the first—would teach us what and how great changes in the figure of the earth's surface are produced by the bodies so moved, through reciprocal action on each other. Sensible of this inevitable reform in dynamic geology, the author of an essay entitled "The Action of the Winds on the Configuration of the Earth," sought to call attention to the gaps hitherto existing in physical geography, and especially to show what a mighty and yet hitherto very little observed agent the wind is, considered as one of these secondary geological forces. In the following paper the author offers to the readers of NATURE a *résumé* of his memoir.

It is at once evident and conformable to nature that the winds are to be regarded, in the first instance, as a proof of the unequal insolation at different points of the earth's surface, but, in their direction and variation, they are immediately influenced now by the position of the sun, now by the earth's rotation and the distribution of the solid and the liquid; that the winds are, on the one hand, a product of these geophysical actions, and, on the other, become a special factor, of which not only the meteorologist, but also, in front rank, the geologist, is called on to take account. Since, that is to say, it is purely the winds which determine the condition of moisture of the atmosphere, and have to perform the *rôle* of distribution of rain over the entire surface of the earth, but at the same time, in their constant circulation from the equator to the poles and from the poles to the equator, represent an imposing motive force, it is obvious that to be able to prove and establish more fully their geological *rôle*, one must consider them in this twofold relation; on the one hand as a climatic-meteoric, on the other as a mechanical agent. Accordingly the essay referred to treats, in its first part, of the climatic-meteoric, in the second, of the mechanical action of the winds; while the third part comprehends those actions of the winds which they perform indirectly either in meteorological or in mechanical relation.

More particularly the *First Part* is concerned with the characteristics of the two principal wind systems, the polar and equatorial currents, and with their reaction on those continents and mountain-chains, by which, in their typical course—as is manifest on oceans and neighbouring coasts, especially west coasts, of continents—they are variously disturbed. The equatorial currents here appear as properly the distributors of precipitation, and therefore as the principal factors by which the transporting power of flowing water, or generally the levelling action of water on the earth's surface, is produced. The polar currents, on the other hand, discover a tendency to act contrary to the work of the equatorial currents, that is, to restore the precipitated water in vapour form to the atmosphere, and generally to further evaporation. In view, however, of the fact that not all the water, which by action of the winds is precipitated on the solid land, returns to the ocean or the atmosphere, these two air-currents together appear to be similarly empowered to empty entirely, some time, the immense water-basin of the earth from which they continually procure anew their freight of water, and meanwhile to continuously lower the sea-level, through by a very small quantity, and therefore to take a prominent part in the so-called secular elevation of continents.

These two air-currents, indeed, are not everywhere and always true to the character just given. On the contrary, when they have to accomplish a great work, and especially when a polar current has to rise over a lofty mountain, or an equatorial current has to traverse an extended surface of dry land, the former, as a rule, even appears as a rainy wind, while the latter, if its course have been *long* enough, appears as a dry wind; and if the mountain range be high enough, which the latter is required to rise over, this may, when it has reached the other side, even stream down as a hot, withering wind, the föhn of Continental writers, on the thirsty regions. If, then, we find in coast districts a greater yearly rainfall than further inwards, or if, on the wind side of the hills, we find lower snow-lines and further-reaching terminal moraines of the glaciers than on the lee side; or lastly, if we find successively regions of forests, of steppes, and of wastes, we may easily recognise therein each time an expression of the power of the winds, which, according as they are abundantly or poorly laden with aqueous vapour, or even quite dry, call forth this variety of geophysical phenomena.

---

[1] Abstract, by Dr. Francis Czerny, of a memoir of his in the 48th supplementary number of Petermann's *Mittheilungen*.

The ever-moving atmosphere has therefore the most heterogeneous actions. While it feeds the glaciers and rivers, it causes at the same time a backward prolongation of these to the common source of the water—to the ocean, so as, with its moist breath, to produce everywhere simultaneously a formation of humus, and awake all into life; and again, where it is otherwise—where it appears as by nature a dry wind, or has been deprived of its freight of water, it brings with it drought and death. In the deserts the flora and fauna, then, have an extremely poor existence; the rivers no longer flow in a regular course; they have already been long in retreat, or are still only intermittent in their flow; the lakes also, when they are to be found in deserts, continually lose, through the constant evaporation, an abundance of water, although they may long have ceased to have an outlet to the neighbouring sea. In many deserts you do not meet with a single brook or pond; instead of such, you find only dried-up wadis and depressions, while the extensive stretches of waste, covered with salt incrustations and efflorescences, as also the scattered remains of dead animal species of past times, give evidence that these waste and withered regions formerly wore quite a different physiognomy; indeed, as the fossils and deposits of gypsum and salt testify, must even have been flooded with enormous inland seas. Now, probably (next to solar heat), it was above all, the winds, especially the dry winds, which, acting for a long period of time in the earth's history, dissolved these seas into aqueous vapour, carried them away, and so transformed the former lake bottom, now laid bare, into a waste.

Second Part.—But the winds are not only an expression for the general circulation of the air and aqueous vapour of the ocean; they are also a moving agent *quand même* not to be underestimated, since, in their progress, they communicate their own motion to all bodies which are not heavy enough to withstand them. Now, according as, in this way, solid or liquid bodies (especially the waters of the ocean) are put in motion, the mechanical action of the winds is to be considered from two distinct standpoints; first, its action on the solid land, and second, on the water, and through this again upon the solid land.

In the first case, it is the conditions of the strata that are continually altered under the action of the winds. It is at one time the snow, at another the salt-dust, at another the vegetable and animal remains, the ashes thrown out in volcanic eruptions, masses of dust and *débris*, or lastly, sand, that are whirled about, raised, carried miles away, and again deposited. The so-called wind-bedding characterises in every case the formations so produced, or in course of production. We shall cite here only two of the most remarkable examples of this kind of power in winds. One is the extensive Chinese Loess formation, which, according to von Richthofen's researches, appears to be quite a wind-formation; the other is the progressive dune-formation and dune-shifting on flat sandy coasts. Closer investigations (in this connection) of the conditions under which dunes are generally formed, examinations of their form, slope, and strike, and further, some materials furnished in the narratives of travel of Rohlfs and Dr. Tietze, have enabled the author to form a new theory as to the origin of sandy wastes, but especially to show that, as a rule, they are simply dune-formations on the shores of the former inland lake which has disappeared through evaporation. Some examples of sand scratches, sand cuttings, and the devastations wrought by hurricanes, illustrate the further mechanical action of the winds on the dry land.

Passing to the mechanical action of winds on water, we have, above all, to consider drift-currents (wind-drifts) and the motion of wind-waves. But while the former manifest themselves as powerful factors of transport, the wind-waves are besides characterised by a not unimportant effect in the direction of depth, but more especially by their now land-forming, now land-shattering surge. In this way the waters appear also as the most powerful medium through which the action of the winds is exerted on the solid land. In fact it is the capricious wind-wave that destroys and carries away whole stretches of coast in order to raise somewhere else and lay dry whole areas out of the oceanic depths (sand bars, sandbanks, flat coasts, delta formations, &c.). It is the wind-wave that ever renders active the principle of constant transformation in opposition to that of stability, and seeks to alter the contours of the dry land. Not without reason, then, does El. Reclus remark:—"It is by the movement of the atmosphere that we have to explain the form of continents." (*C'est par les mouvements de l'atmosphere, qu'il faut expliquer la forme des continents.*)

Third Part.—The winds, finally, produce, in an indirect way, many geological phenomena. According as they influence and determine the air-pressure, they cause now a perceptible swelling out, now a sinking of some large water surface, as has been observed on the oceans as well as on the North American and the Swiss lakes. Through this influence of air-pressure the winds further appear to affect volcanoes now favourably, now preventively—since also the lava masses in the crater (according to P. Scrope's representation) must be sensitive to atmospheric pressure; in high pressure finding a greater resistance, and in low pressure rising and breaking out more easily. The firedamp explosions also appear to be favoured by barometric depression. Similarly a certain connection can be demonstrated between the air-pressure and earthquakes.

Still more evidently are winds seen to exert an influence on earthquakes and volcanic phenomena, when regarded as rain-winds. With a large access of atmospheric water are connected both subterranean deluges and overturnings, and an abundant formation of steam in the heart of volcanoes; these circumstances immediately give rise to earth-tremblings, or violent volcanic outbursts and exhalations of steam.

If the hypothesis of T. R. Mayer, that the trade-winds are the principal cause of terrestrial magnetism, be correct, we must also, finally, ascribe to the winds an important part in the production of electricity. Lyon, Duveyrier, and Rohlfs have observed that the dry desert wind is uncommonly rich in electricity.

The author, indeed, has, in the course of his researches, given attention especially to the action of the winds in the most recent geological periods, and must in the meantime leave to specialists the more definite answering of the question how far the traces of action of winds also in the older periods of the earth's history can be followed. It is certain, however, that since in historical geology we have to do with a land flora and fauna, and with the (wrongly) so-called ocean precipitate, and so with the building up of sedimentary layers, we have so many undoubted proofs of the existence of rain and rivers, and accordingly of that of winds. Even when the earth was still a ball of glowing gas—and consequently a sort of sun to the moon's inhabitants, we can conceive the wind already acting as a geological agent—with the proviso, indeed, that the theory (of Faye and Keye) which regards the sun-spots as cyclone-like phenomena, or Secchi's view that the temperature of the sun at the sun's equator is higher than beyond the 30th degree of latitude, be verified.

UNDERGROUND TEMPERATURE[1]

A REMARKABLE series of observations have recently been taken in a boring at Sperenberg, near Berlin. The bore was carried to the depth of 4,052 Rhenish (or 4,172 English) feet, and was entirely in rock salt with the exception of the first 283 feet, which were in gypsum with some anhydrite. The observations were taken under the direction of Herr Eduard Dunker, of Halle-an-der-Saale, and are described by him in a paper occupying thirty-two closely printed quarto pages (206-238) of the *Zeitschrift für Berg-Hütten-und-Salinen-Wesen* (xx. Band, 2 und 3 Lieferung, Berlin, 1872).

---

[1] Ninth Report of the British Association Committee, consisting of Prof. Everett, Sir W Thomson, F.R.S, Prof. J. Clerk Maxwell, F.R.S., G. J. Symons, F.M.S., Prof. Ramsay, F.R.S., Prof. A. Geikie, F.R.S., James Glaisher, F.R.S., George Maw, F.G.S., W. Pengelly, F.R.S, Prof. Hull, F.R.S., Prof. Ansted, F.R.S., Prof. Prestwich, F.R.S., Dr. C. Le Neve Foster, Prof. A. S. Herschel, G. A. Lebour, F.G.S., and A. B. Wynne, appointed for the purpose of investigating the Rate of Increase of Underground Temperature downwards in various Localities of Dry Land, and under Water. Drawn up by Prof. Everett, Secretary.

The instrument employed for measuring the temperatures was he earth-thermometer of Magnus, which gives its indications by he overflowing of mercury, which takes place when the instruient is exposed to a higher temperature than that at which it vas set. To take the reading, it is immersed in water a little older than the temperature to be measured; the temperature of his water is noted by means of a normal thermometer, and at the ame time the number of degrees that are empty in the earth-hermometer is noted. From these data the maximum tempeature to which the instrument has been exposed can be deduced, ubject to a correction for pressure, which is not very large, ecause the same pressure acts upon the interior as upon the xterior of the thermometer.

In the following *résumé* (as in the original paper) temperatures re expressed in the Réaumur scale, and depths in Rhenish feet, he Rhenish foot being 1·029722 English foot.

Observations were first taken at intervals not exceeding 100 feet, rom the depth of 100 feet to that of 4042 feet, the temperature bserved at the former depth being 11·0, and at the latter 38·5; ut all these observations, though forming in themselves a smooth eries, were afterwards rejected, on the ground that they were itiated by circulation of water and consequent convection of eat.

It has often been supposed that though this source of error nay affect the middle and upper parts of a bore, it cannot affect he bottom; but the Sperenberg observations seem to prove that no such exemption exists. When the bore had attained a depth of early 3,390 feet, with a diameter of 12 inches 2 lines at the ottom, an advance bore of only 6 inches' diameter was driven 7½ feet further. A thermometer was then lowered half-way own this advance bore, and a plug was driven into the mouth f this advance bore so as to isolate the water contained in it rom the rest of the water above. After twenty-eight hours the lug was drawn and the thermometer showed a temperature of 36·6. On the following day the temperature was observed at he same depth without a plug, and found to be 33·6. Another bservation with the plug was then taken, the thermometer (a resh instrument) being left twenty-four hours in its position. It egistered 36·5, and again, without plugging, it gave on the same ay 33·9. It thus appears that the effect of convection was to ender the temperature in the advance bore 3° R. too low.

Apparatus was then employed for isolating any portion of a ore by means of two plugs at a suituble distance apart with the hermometer between them. This operation was found much nore difficult than that above described, but in several instances t gave results which were deemed quite satisfactory; while in ther instances the apparatus broke, or the plugging was found mperfect. The deepest of the successful observations by this nethod was at 2,100 feet, and the shallowest was at 700 feet. The first 444 feet of the bore was lined with iron tubes, between which the water had the opportunity of circulating even when he innermost tube was plugged, hence the observations taken in his part were rejected.

All the successful observations are given in the third column f the following table, subject to a correction for pressure; and, or the sake of showing the error due to convection in the ordinary mode of observing, the temperatures observed at the same epths when no plugs were used, are given in the second olumn:—

Depth in feet.	Temperature Réaumur.		Difference.
	Without plugging.	With plugging.	
700	16·08	17·06	0·98
900	17·18	18·5	1·32
1,100	19·08	20·8	0·72
1,300	20·38	21·1	0·72
1,500	22·08	22·8	0·72
1,700	22·9	24·1	1·2
1,900	24·8	25·8	1·0
2,100	26·8	27·1	0·3
3,390	34·1	36·15	2·05

These temperatures are not corrected for pressure, but they re corrected for rise of zero in the normal thermometer; and his last circumstance explains the difference of 0·4 between the temperature 36·15 here given and 36·55, which is the mean of the above-mentioned observations at the depth of 3,390 feet.

Another proof of the injurious effect of convection was obtained by comparing the observed temperatures (without plugging) in the first 400 feet of the great bore, designated Bore I., with the temperatures observed at the same depths during the sinking of another bore, designated Bore II., near it; the observations in this latter being always taken at the bottom. The following were the results:—

Depth Feet.	Temperatures.	
	Bore I.	Bore II.
100	11·0	9·0
200	11·6	10·4
300	12·3	11·5
400	13·6	12·5

The temperature at the depth of 100 feet in the great bore thus appears to have been raised about 2° R. by convection.

The following is a table of the successful observations, corrected for pressure:—

Depth in Rhenish feet.	Temperature Réaumur.
700	17·275
900	18·780
1,100	21·147
1,300	21·510
1,500	23·277
1,700	24·741
1,900	26·504
2,100	28·668
3,390	37·238

Assuming, with Herr Dunker, the mean temperature of the surface to be 7·18, which is the mean annual temperature of the air at Berlin, we have the following increments of temperature with depth:—

Depths in Rhenish feet.	Increment of depth.	Increment of temperature.	Increase per 100 feet deg. Réau.	Increase per 100 feet deg. Fahr.
0 to 700	700	10·095	1·442	3·24
700 to 900	200	1·505	·752	1·69
900 to 1,100	200	2·367	1·184	2·66
1,100 to 1,300	200	0·363	·182	·41
1,300 to 1,500	200	1·767	·884	1·99
1,500 to 1,700	200	1·464	·732	1·65
1,700 to 1,900	200	1·763	·882	1·98
1,900 to 2,100	200	2·164	1·082	2·43
2,100 to 3,390	1,290	8·570	·664	1·49
0 to 3,390	3,390	30·058	·887	2·00

The mean rate of increase found by comparing the temperatures at the surface and 3,390 feet is exactly 1° Fahr. for 50 Rhenish or 51·5 English feet.

The numbers in the last two columns exhibit upon the whole a diminution with increase of depth; in other words, the temperature increases less rapidly as we go deeper down. As regards the first 700 feet, which exhibit a decidedly more rapid rate than the rest, it must be remembered that nearly half of this distance was in a different material from the rest of the bore, being in gypsum with some anhydrite, while all the rest was in rock salt. Prof. Herschel has found, in recent experiments not yet published, that the conductivity of rock salt is exceedingly high; and theory shows that the rates of increase, in superimposed strata, should be inversely as their conductivities. We may, therefore, fairly attribute the rapid increase in the first 700 feet to the relatively small conductivity of the portion (283 feet) which is not rock salt. The slow rate of increase observed in the long interval between the depths of 2,100 and 3,390 feet is not so easily accounted for; we can only conjecture that this and the other inequalities which the above table presents, for depths exceeding 700 feet, are due to fissures or other inequalities in the rock which have not been put in evidence.

With the view of summing up his results in small compass, Herr Dunker has assumed the empirical formula—

$$t = 7{\cdot}18 + ax + bx^2,$$

t denoting the temperature (Réaumur) at the depth x (Rhenish feet); and has computed the most probable values of a and b, by the method of least squares. He finds

$$a = {\cdot}0129857 \qquad b = -\,{\cdot}000000125791,$$

the negative sign of b indicating that the increase of temperature becomes slower as the depth increases.

A paper by Prof. Mohr, of Bonn, as represented by an abstract published in NATURE (vol. xii. p. 545), has attracted attention from the boldness of its reasoning in reference to the Sperenberg observations. Prof. Mohr, however, does not quote the observations themselves, but only the temperatures calculated by the above formula, which he designates, in his original paper (*Neues Jahrbuch für Mineralogie*, &c., 1875, Heft 4), "the results deduced from the observations by the method of least squares." In the abstract in NATURE they are simply termed "the results of the thermometric investigation of the Sperenberg boring," a designation which is still more misleading.

Attention is called to the circumstance that the successive increments of temperature for successive equal increments of depth, form an exact arithmetical progression, as if this were a remarkable fact of observation, whereas it is merely the result of the particular mode of reduction which was adopted, being a mathematical consequence of the assumed formula $t = 7{\cdot}18 + ax + bx^2$. The method of least squares is not responsible for this formula, but merely serves, after this formula has been assumed for convenience, to give the best values of a and b.

Herr Dunker, in his own paper, lays no stress upon the formula, and gives a caution against extending it to depths much greater than those to which the observations extend. Writing to Prof. Everett under date April, 1876, he requests that in the summary of his results to be given in the present Report, the formula should either be suppressed or accompanied by the statement that its author reserves a different deduction.

The following are the differences between the temperatures computed by the formula and the observed temperatures:—

Depth.	Difference (computed *minus* observed).
700	− 1·621
900	− 0·931
1,100	− 1·204
1,300	+ 0·427
1,500	+ 0·553
1,700	+ 0·882
1,900	+ 0·811
2,100	+ 0·238
3,390	+ 0·482

The necessity of adopting some means to prevent the circulation of water in bores, has for some time been forcing itself upon the attention of your Committee. Many of the observations taken by their observers have contained such palpable evidence of convection as to render them manifestly useless for the purpose intended; and in the light of the Sperenberg experiments it is difficult to place much reliance on any observations taken in deep bores without plugging. The selection of a suitable form of plug is now occupying the careful attention of your Committee.

Herr Dunker's paper gives a very full account of the different kinds of plug employed at Sperenberg.

For stopping the mouth of the advance-bore the plug had a tapering shape, and was of hard wood, strengthened by two iron rings, one at each end, and covered with a layer of tow 5 lines thick, outside of which was thick and strong linen, nailed above and below to the wood, through a leather strap. It was lowered into its place by means of the iron rods used for boring; and, when in position, was pressed home by a portion of the weight of the rods. The plug carried the thermometer suspended from it. Its extraction was commenced by means of a screw on the beam of the boring machine, in order to avoid a sudden jerk, which might have broken the thermometer. The force which was found necessary for thus starting the plug, as well as the impression observed upon it when withdrawn, showed that it had fitted tight. To insure a good fit, the top of the advance-bore had been brought to a suitable shape, and its inequalities removed, by means of a revolving cutting-tool. Herr Dunker remarks that this plan is adapted to a soft material like rock-salt, but that in ordinary hard rock it would be better to make the bottom of the main bore flat, and to close the advance-bore by an elastic disc pressed over it. The method of observation by advance-bores can only be employed during the sinking of the bore, a time when it is difficult to avoid error arising from the heat generated in boring. The expense of making an advance-bore at each depth at which an observation is required is also an objection to its use.

Another kind of plug devised by Herr Dunker, and largely used in the observations, consisted of a bag of very stout india-rubber (9 millimetres thick) filled with water, and capable of being pressed between two wooden discs, one above and the other below it, so as to make it bulge out in the middle and fit tightly against the sides of the bore. On the suggestion of bore-inspector Zobel, the pressure was applied and removed by means of screwing. Two steel springs fastened to the upper disc, and appearing, in Herr Dunker's diagram, very like the two halves of a circular hoop distorted into an oval by pressing against its walls, prevented the upper disc from turning, but offered little resistance to its rising or falling. The lower disc, on the contrary, was permitted to turn. Both discs were carried by the iron boring-rods. Rotation of these in one direction screwed the discs nearer together, and rotation in the other direction brought them further apart. The india-rubber bag could thus be made to swell out and plug the bore when it was at the desired depth, and could be reduced to its original size for raising or lowering. In order to prevent the boring-rods from becoming unscrewed one from another, when rotated backwards, it was necessary to fasten them together by clamps, a rather tedious operation in working at great depths.

In taking observations at other points than the bottom, two of these plugs were employed, one above and the other below the thermometer.

In some of the experiments, the apparatus was modified by using linen bags filled with wet clay, instead of indian-rubber bags filled with water; and, instead of screwing, direct pressure was employed, the lower disk being supported by rods extending to the bottom of the bore, while the upper disk could be made to bear the whole or a portion of the weight of the rods above it. Some successful observations were obtained with both kinds of bag; but the water-bags were preferred, as returning more easily to their original size when the pressure was removed, and consequently being less liable to injury in extraction. In some observations since taken in another place (Sudenberg), Herr Dunker states (in the private letter above referred to) that indian-rubber bags, filled with water, and pressed, not by screwing, but by the weight of the rods, were employed with much satisfaction.

All the methods of plugging employed by Herr Dunker involved the use of the iron rods belonging to the boring apparatus, and therefore would be inapplicable (except at great expense) after the operation of boring is finished and the apparatus removed.

It seems desirable to contrive, if possible, some plug that ca be let down and raised by a wire. In the first report of you Committee, it was suggested that two bags of sand, one abov and the other below the thermometer, should be used for thi purpose. Bags of sand, however, would be liable to rub o pieces from the sides of the bore, and thus to become jammed i drawing up. Mr. Lebour has devised a plug which will be of smal diameter during the processes of lowering and raising, but can b rendered large and made to fit the bore, when at the prope depth, by letting down upon it a sliding weight suspended by second wire. Sir W. Thomson suggests that a series of indian rubber disks, at a considerable distance apart, will probably b found effectual.

Mr. Boot has continued his observations in the bore which h is making at Swinderby, near Scarle (Lincoln). It has now bee carried to the depth of 2,000 feet, and is in earthy limestone calcareous shale, of carboniferous age. Its diameter in th lower part is only 3½ inches. In April last the temperatur 78° F., was observed at 1,950 feet; and more recently 79°

was observed at 2,000 feet; the water, in each case, having been undisturbed for a month. Supposing these results not to be vitiated by convection, and assuming the mean temperature at the surface to be 50°, we have an increase of 29° in 2,000 feet, which is at the rate of 1° in 69 feet.

Mr. Symons has taken a series of observations at the depth of 1,000 feet in the Kentish Town well, with the view of determining whether the temperature changes. The instrument employed is a very large and delicate Phillips' maximum thermometer. The following is a list of the observations:—

Date of lowering.	Depth indicated. Feet.	Thermometer set at.	Date of raising.	Depth indicated. Feet.	Temperature. Fahr.
1874 —	1000	64·50	May 8	1007	66·82

,, Nov. 1	1000	63·70	Dec. 1	Wire broke.	

The "depth indicated" is shown by a measuring wheel or pulley, over which the wire runs by which the thermometer is raised and lowered, as described, with a diagram, in the Report for 1869. The above table shows that there is always some stretching, real or apparent, in the interval between lowering the thermometer and raising it again. Recent observations by means of a fixed mark on the wire, have shown that the change is not, in the main, a permanent elongation, but an alternation of length. It is probably due in part to the greater tension which the wire is under in raising than in lowering, a circumstance which will cause a temporary difference of length variable with the rapidity of winding up; also in part to the circumstance that the wire is warmer when it has just left the water than when it is about to be let down. Some portion of the irregularity observed may be due to variations of temperature in that part of the well (210 feet) which contains air. The observations taken as a whole, show that any variations of temperature which occur in this well at the depth of 1,000 feet, are so small as to be comparable with the almost inevitable errors of observation. The observations will be continued at intervals of six months, with additional precautions, and with an excessively slow (specially constructed) non-registering thermometer, in addition to the maximum thermometer hitherto employed.

Through the kindness of the eminent geologist, M. Delesse, of the Ecôle Normale at Paris, observations have been obtained from the coal-mines of Anzin, in the north of France. They were taken under the direction of M. Marsilly, chief engineer of these mines. Maximum thermometers of the protected Negretti pattern, were inserted in holes bored horizontally to the depth of ·6 or ·7 of a metre in the sides of shafts which were in process of sinking, and in which there was but little circulation of air. A quarter of an hour was allowed to elapse in each case, after the boring of the hole, before the thermometer was inserted, and the hole plugged. Four different shafts were tried. Those designated as Nos. I., II., III., were in the mine Chabaud La Tour; and No. IV. was in the mine Renard.

In Shaft I. observations were taken at eight different depths, commencing with the temperature 56¼° F. at the depth of 38·5 metres, and ending with 67¾° F. at 200·5 metres.

In Shaft II. there were observations at four depths, commencing with 55° at 87·3 m., and ending with 63¼° at 185 m.

In Shaft III. there were observations at three depths, commencing with 56° at 87·8 m., and ending with 62½° at 144 m.

These three shafts, all belonging to the same mine, were very wet, and the temperature of the air in them was 11° or 12° C. (52° or 54° F.).

In Shaft IV., which was very dry and had an air temperature of about 15° C. (59° F.), observations were taken at 6 depths, commencing with 70¾° F. at 21·2 m., and ending with 84° F. at 134·8 m.

The mean rates of increase deduced from these observations are:—

In Shaft	I.,	1° F. in	14·4 m.,	or in	47·2 feet.
,,	II.,	,,	11·5 m.,	,,	37·7 ,,
,,	III.,	,,	8·65 m.,	,,	28·4 ,,
,,	IV.,	,,	8·57 m.,	,,	28·1 ,,

The observer mentions that in Shaft II. there was at the depth of 90 m. a seam of coal in which heat was generated by oxydation; but no such remark is made with respect to any of the other shafts, although it is obvious that some disturbing cause has rendered the temperatures in Shaft IV. abnormally high. Possibly the heat generated in boring the holes for the thermometers in this shaft (which was dry) has vitiated the observations, the instruments employed being maximum thermometers. Two of the slow non-registering thermometers mentioned in last year's Report have been sent to M. Delesse, to be used for verification.

The slow-action thermometers are constructed on the following plan:—The bulb is cylindrical and very strong, and is surrounded by stearine or tallow, which fills up the space between it and a strong glass shield in which the thermometer is inclosed. The shield is not hermetically sealed (not being intended for protection against pressure), but is stopped at the bottom with a cork, so that the thermometer can be taken out and put in again if desired. Stearine and tallow were selected, after trials of several substances, including paraffin-wax, bees'-wax, glue, plaster of Paris, pounded glass, and cotton wool. The thermometers are inclosed in copper cases lined with india-rubber. When placed, without these cases, in water differing 10° from their own temperature, they take nearly half a minute to alter by one-tenth of a degree.

In concluding this Report, your Committee desire to express their regret at the losses which they have sustained by the deaths of Prof. Phillips, Sir Charles Lyell, and Col. Strange, of whose valuable services they have been deprived within the last three years.

OUR ASTRONOMICAL COLUMN

THE ROTATION OF SATURN ON HIS AXIS.—On December 7 Prof. Hall, of the Naval Observatory at Washington, observed a very white spot on the disc of Saturn, just below the ring. At 6h. 18m., Washington mean time, the spot was central, and it was watched from 22h. 40m. sidereal time, to 0h. 10m., as it moved across the disc. It was small, very well defined, and from 2″ to 3″ in diameter. A rough ephemeris of its motion was sent to various observers in the U.S., and the observations which have been received are as below. The second column gives the time when the spot was central.

	Washington. M.T. h. m.	Place.	Observer.	o − c
1876, Dec. 7	6 18	Washington	Hall	...
10	6 11	Cambridge	A. G. Clark ...	− 8m
—	6 3	Hartford	D. W. Edgecomb	0
—	6 4	Poughkeepsie	M. Mitchell ...	− 1
—	...	Albany	L. Boss	...
13	5 47	Washington	Hall	0
—	5 50	,,	Eastman	... 3
—	5 38	Cambridge	A. G. Clark ...	+ 9

The column o − c gives the residuals when a rotation-time of 10h. 15m. is assumed. At Albany, on December 10, the spot was seen, but not until after passing the centre.

[It will be remarked that the time of rotation, supported by the above observations of a very definite spot, is in close agreement with the result obtained by Sir W. Herschel from noting the successive appearances of a belt during the winter of 1793-94.

viz. 10h. 16m. 0·4s. Doubt has been occasionally expressed with regard to Sir W. Herschel's rotation-period from the uncertainty attaching to such observations, and the interesting confirmation of it just arrived at by the American observers will therefore be the more welcome. The Herschelian rotation for the planet globe of Saturn has been sometimes confounded with a rotation not depending upon observations, but calculated on Kepler's law for a satellite at an apparent mean distance equal to the semi-diameter of the middle of the ring; thus, Baily, in his "Astronomical Tables and Formulæ"—which were widely quoted for many years—has 10h. 29m. 17s. for time of rotation both of the globe and the ring.]

The Nebula in the Pleiades.—Mr. Maxwell Hall, of Jamaica, communicates some observations of this nebula made on October 20, 1876, with a 4-inch Cooke equatorial, and power 55. "The nebula was 'bright,' according to Sir John Herschel's scale, and extended in a parabolical form at least 40′ from Merope, which was at the focus, while the axis of the figure was nearly S. of that star."

The difficulty of seeing with very large instruments a very faint nebulosity in close proximity to a bright star is strikingly illustrated by a remark made by Mr. Dreyer, observing with Lord Rosse; he states—"The Merope-nebula is never perceived with Lord Rosse's telescopes." So also D'Arrest sought for it in vain with the Copenhagen refractor, subsequently referring it to the class of which we are writing, which may be invisible in a great telescope but seen without difficulty in the finder. Vols. lviii. and lix. of *Astronomische Nachrichten* may be consulted for the earlier discussions as to the variability of this object.

Variable Stars.—Prof. Schönfeld has published in *Vierteljahrsschrift der astronomischen Gesellschaft*, xi. Jahrgang, Heft 4, an ephemeris of the maxima and minima of most of the variable stars for 1877, including Algol, λ Tauri, S Cancri, δ Libræ, and U Coronæ Borealis, which have short periods. The max. of χ Cygni is dated February 6, and the min. on September 15; Mira Ceti, min. on July 23, max. on November 10.

Schmidt's star in Cygnus was red on January 7, and about equal in brightness to the star + 41° No. 4243 in the "Durchmusterung," but the difference of only 0·5m. between the catalogue brightness of this star and that of + 42° No. 4204, certainly did not represent their relative intensity of light on this evening. The variable might be estimated at 7·2m. by reference to the latter star.

Meteors of January 7.—In the early part of this night a number of meteors were remarked near London, with unusually slow motion, particularly in the cases of several which equalled Jupiter in brightness. One at 10h. 32m. G.M.T. starting from near λ and μ Ursæ Majoris, appeared to receive a sudden check, and was stationary for two seconds 3° below α Canum Venaticorum, where it was nearly extinguished, but a faint portion left a train for several degrees further. It was not easy to judge of the radiant point owing to continual interruption from passing clouds, but it would probably be somewhere about the stars in Ursa Major above-named. Much lightning on this evening. The zodiacal light well seen as far as the principal stars of Aries.

The Melbourne Observatory.—The Eleventh Report of the Board of Visitors of the Melbourne Observatory, with Mr. Ellery's Annual Report for the year ended 1876, June 20, has been received. In addition to the large reflectors, the Observatory now possesses an 8-inch equatorial, both instruments in excellent working order. With respect to the former, Mr. Ellery remarks that, although at present the mirrors retain their high reflecting polish exceedingly well, it is not to be overlooked that the time must arrive when they will require to be repolished, and in anticipation of this eventuality, which may occur sooner than is now looked for, he intends to devote time during the ensuing year to practice in grinding and polishing large surfaces. Out of about 150 nights during the year to which the report applies, which were more or less fit for observing with the reflector, forty were solely occupied with visitors. The astronomical work accomplished includes the examination, measurement, and sketching of seventy of the nebulæ and clusters of Sir John Herschel's southern work, of which the greater number have been drawn and described in a manner suitable for publication. Mr. Ellery adds:—"The result of these observations indicates that several of the nebulæ are considerably changed, while others appear so completely altered as to be scarcely recognisable, save by their position with respect to adjacent stars. The nebula about η Argus have been compared with a drawing made in March, 1875, but no decided changes were detected. The weather was so far unfavourable at Melbourne for certain classes of observations that out of ninety conjunctions of Saturn's satellites only ten could be observed. No material change in the regular work of the Observatory is contemplated during the year following the conclusion of the report. Observations with the transit-circle would be continued assiduously as in previous years, the Government Astronomer regarding this as the fundamental work of the establishment, which has already given it a reputation in the world, and he quotes in proof of this the opinion expressed by Sir George Airy, that the Melbourne Observatory had produced "the best catalogue of stars of the southern hemisphere ever published." The revision of Sir John Herschel's figured nebulæ will also be continued, with occasional planetary work, as drawings of Mars and Jupiter, observations of conjunctions of Saturn's satellites, &c.

The early publication of results obtained with the great reflector is strongly urged by Mr. Ellery, and all astronomers will concur in his representations upon this point. Difficulties, no doubt, must exist in giving such results to the astronomical world in a perfectly satisfactory manner; nevertheless, Mr. Ellery thinks if a plan he proposes is approved, these difficulties may be surmounted, and all the completed work with the reflector may be forthwith published. We can only express the hope that work of such great interest, and which may so greatly add to the reputation of the Melbourne Observatory, will soon be in the hands of the public. The importance of early publications of astronomical work in these days can hardly be exaggerated.

METEOROLOGICAL NOTES

New Daily Weather Map.—We hail with the greatest satisfaction the appearance, on New Year's Day, of the first number of a daily international weather-map issued by the Austrian Meteorological Institute. It embraces nearly the whole of Europe, and supplies a want not met by any existing weather-maps, in representing the weather of Central and part of Southern Europe, with a satisfactory fulness such as the meteorology of this important region demands in the development of this branch of the science. In addition to the invaluable material this publication will lay before us from day to day relating to thunderstorms, the summer rains, and the falls of hail and snow of Central Europe, it will also furnish data absolutely indispensable in investigating the causes which determine the course and the rate of progress of the storms of North-western Europe. Indeed, in this respect, and consequently in the prognosis of British storms, the Austrian empire is, of all countries which lie eastwards of Great Britain, second in importance only to Lapland and the north of Scandinavia.

Low Temperatures.—During recent weeks some remarkably low temperatures have been recorded in various countries. During a heavy storm which occurred on December 17 over all Canada and the north of the United States, and which was attended with considerable damage, the temperature fell at Ottawa to – 30°·0. What makes this temperature noteworthy is that at the same time the wind continued to blow with great violence, the low temperature being thus not confined to a few feet of the surface, but that of the aërial current passing over Ottawa at the time. On January 4 the temperature fell at Hernösand, in Sweden, and also in Lapland to – 31°·2. An anticyclone of limited extent, with the characteristic calms and light winds, overspread this region at the time, and it is to be noted that the space of excessively low temperature embraced an area virtually coincident with, and equally as limited as, that of the anticyclone. Still lower temperatures are reported from the interior of Russia. The *Golos* gives the following information as to the unusually low temperatures which prevailed in Northern Russia before Christmas. The thermometer of the Physical Observatory at St. Petersburg (in town) showed on the 22nd, at 9 A.M., – 37°·8 Cels., and in the Botanical Garden (in the suburbs), between 7 and 9 A.M., the following temperatures were observed:— – 38°·1 on the 20th, – 39°·4 on the 21st, and – 41°·9 on the 22nd (– 43°·4 Fahr.) On the last-named day the mercury was frozen, and the readings were made from a spirit thermometer. So low a temperature as on the 22nd was never observed before at St. Petersburg in December, during the 123 years that regular meteorological observations have been made; and even during the coldest month, January, such low temperatures were observed before only four times, namely, – 38° on January 26, 1868; – 41° in 1760; – 38°·7 in 1772; and – 39°·0 in 1814. The region of low temperatures occupied a very large tract of land, and the cold advanced from the north-east, as was also the case during the unusual cold of 1868. On the 22nd there was observed in the morning, – 40°·4 at Vologda, – 40°·5 at Kuopio, in Finland, – 39°·9 at Bielozersk, – 39° in Moscow (– 40° in the higher parts of the town), &c. Very low temperatures might have been predicted for some days before, as already on the 20th the cold reached – 44° Cels. (– 47° Fahr.) in Vologda, and the barometer continued to rise in the whole of Northern Europe, whilst a minimum of pressure traversed the middle parts of Europe and Southern Russia, with comparatively high temperatures and cyclonic winds, which in the north and on the shores of the Baltic blew from the east and the north.

NOTES

A WEALTHY Copenhagen brewer, J. C. Jacobsen, has given the sum of a million of crowns for the promotion of mathematics, natural science, the science of language, history, and philosophy.

AS we intimated some time since, the Swedish University of Upsala, founded September 21, 1477, will this year celebrate its 400th anniversary. Great preparations are being made for the event. The University is not only the oldest but the richest in Scandinavia; besides many rich gifts from Gustavus Vasa, it received, among other things, from Gustavus Adolphus, 360 farms, which now yield an annual rent of 200,000 crowns. The funds for maintenance and salaries amounted, in 1870, to 1,758,587 crowns, and the yearly Government grant to 300,000 crowns. The teaching staff consists of thirty-five professors, twenty-seven adjuncts, and fifty docents; the number of matriculated students amounts to about 1,500.

THE Royal Cabinet of Natural History at Stuttgart has just been enriched with an exceedingly rare and valuable palæontological specimen, which is probably without its like in the geological museums of the world. It consists of a group of twenty-four fossil lizards from the sandstone strata of Stuben. The inclosing stone has been with great care entirely removed, showing a strangely intertwined mass, possibly as met by sudden death, but more probably a collection of dead bodies gathered together by the action of the waves. They cover a space of about two square yards, and the individual specimens possess an average length of thirty-two inches. These fossils can be classed with no existing species, but appear rather to possess a combination of diverse characteristics, which at a later stage of development became distinctive features of quite different types. Prominent among the peculiarities are the bones of the extremities, resembling those of existing lizards; the head, which can almost be called a bird's head, and the massive scaly armour, consisting of sixty to seventy successive rings.

WE notice with great pleasure that decided steps are about to be taken to reform the curriculum in Exeter Grammar School. It is intended, as soon as arrangements can be completed, that the younger boys shall be taught divinity, English, including history and geography, French, Latin, arithmetic, and the other elements of mathematics, drawing, and some elementary natural science. At a certain point in the school Greek will be added, in accordance with the provisions of the Scheme and the resolution of the Governors; or in lieu of the study of Greek more time will be devoted to mathematics, English, modern languages, and natural science. German will be taught to any boys sufficiently advanced in other subjects to make it desirable. Thus, it is hoped, boys will be adequately prepared for the Universities, for the Public Service, for professional or commercial life. The principle of this new scheme is excellent, and should it be faithfully carried out, Exeter Grammar School ought to become one of the most efficient and complete schools in the country. We hope that the school will receive every encouragement in this laudable effort to provide a complete course of instruction.

THE Vilna Observatory is reported to have been totally destroyed by a fire on December 28. The *Vilensky Vestnik* says that the combined efforts of the town and railway fire brigades, of the troops, and of the students of a college in the neighbourhood, did not succeed in overcoming the fire and rescuing the great refractor and photo-heliograph. Only books and instruments of smaller value were saved. This is a great loss to science, as the Observatory had done, during the last few years, very valuable work, and some of the beautiful photographs of the sun was exhibited at the South Kensington Loan Collection.

MR. F. B. MEEK, the eminent palæontologist, and for several years a member of the United States Geological and Geographical Survey of the Territories, under Prof. F. V. Hayden, died at Washington, D.C., December 21, aged fifty-nine years. He had just completed the great work of his life, the Cretaceous and Tertiary Invertebrate Fossils of the Upper Missouri Country, in one large quarto volume.

IN the last Session of the Berlin *Anthropologische Gesellschaft*, Prof. Virchow stated that the intrepid young traveller, Herr v. Horn von der Horck, is at present in the camps of the warlike Sioux Indians, busily engaged in obtaining plaster casts for craniological studies. The printed record of v. d. Horck's journey of last summer to the Polar Sea, has just appeared in Germany, and contains much of value written in a very sprightly style. During the first half of the journey zoological and geographical ends were kept in view. On the return trip through Lapland to the Gulf of Bothnia, the expedition assumed an almost exclusively anthropological character. Enormous collections of bones and more especially of skulls were made, and a large number of masks were obtained from the present inhabitants of Lapland. So extensive and complete are these results, that Prof. Virchow regards them as more valuable for the study of Scandinavian craniology than the combined collections o

European museums outside of the Scandinavian countries themselves. The principal geographical result of the journey was the establishment of the fact that a continuous water communication exists between the Polar Sea and the Gulf of Bothnia. On the summit of the watershed between these bodies of water, the lake Wawolo Lampi lies at a height of 800-900 feet above the level of the sea. Two rivers flow from this, one to the north, emptying into the Ivalle, and the other to the south, emptying into the Kititui. Frequent cascades and rapids render this waterway useless for purposes of navigation.

PROF. PALMIERI—the *Times* correspondent at Rome telegraphs on January 7—writing from the Observatory on Mount Vesuvius, says that for the last two days the instruments have shown evident signs of agitation. The smoke from the mountain is issuing with greater force and increased volume. In the interior of the last mouth, opened on December 18, 1865, the fire is no longer visible, in consequence of an immense amount of material having fallen into it, through the giving way of a portion of the crater of 1872. An extraordinary eruptive force will, therefore, be necessary either to make a way through the enormous accumulation of sand and scoriæ or to open some new mouth, whether on the summit or the side of the volcano. In the meantime, the cone is manifest, but it cannot be stated when it will reach a point sufficient to overcome the resistance.

M. FAYE has been appointed president of the *Bureau des Longitudes* for 1877, and Dr. Janssen vice-president.

A SUBSCRIPTION has been opened at Rouen for the erection of a statue to M. Pouchet, the naturalist, who was the director of the Botanic Gardens of that city, and who died ten years ago. M. Pouchet, as a correspondent of the Academy of Sciences, published many papers in defence of spontaneous generation against M. Pasteur. His works are referred to by Haeckel and Bastian.

AN Admiralty Committee of Inquiry has been appointed in connection with the outbreak of scurvy in the Arctic expedition.

AT the meeting of the Geographical Society on Monday, Mr. Robert Michell read a paper on "The Russian Expedition to the Alai and Pamir." The expedition resulted in much interesting information, which was mentioned in detail, as to the physical features of the country. The president, in winding up the discussion, observed that the regions visited by the expedition and described in the paper were, perhaps, the least known in Central Asia. They contained vast and confused ranges of mountains, some of the peaks of which were among the highest in the world. He trusted that when further expeditions of the kind were organised, steps would be taken by our government to secure that at least two Englishmen of requisite scientific attainment should be allowed to accompany them.

A RECENT thorough survey of the Kasbek-glacier of the Caucasus, has proved that since 1863 it has increased, *i.e.*, its lower extremity has advanced down the valley, by 826 feet.

THE *Medicinisch-ætiologische Verein* of Berlin decided, in the session of January 4, to call together during the present year an ætiological congress. The following four subjects are announced as the principal topics for the coming conference:—1. Methods of ætiological investigation. 2. Causes of epidemic disease dependent upon mankind. 3. The natural conditions of epidemic diseases. 4. On the *Contagium vivum*.

AT the January session of the Vienna *Zoologisch-botanische Gesellschaft* papers were read by Herr J. Mann "On the Lepidopterous Fauna of the Dolomite Region," and by Prof. Jeitteles "On Treissena Polymorpha."

DR. BREHM, the enterprising Siberian explorer, is at present delivering in the principal German cities, a course of six lectures on the results of his last tour through Northern Asia.

PROF. KLEIN, one of the most promising among the younger German mineralogists, has accepted a call to the professorship of crystallography at the University of Halle.

AUSTRIA follows Germany and other countries in accepting the invitation of the King of Belgium, and an *Afrikanische Gesellschaft* has been organised at Vienna.

THE German Imperial Sanitary Department commences, with the beginning of the present year, the publication of a weekly periodical devoted to sanitary statistics and all subjects connected with the preservation of the public health. Prompt official reports of the mortality in all cities numbering over 150,000 inhabitants, will form a leading feature.

THE Municipal Council of Paris, determined to spare no efforts in order to prevent fresh inundations, have voted the funds for boring a new sewer, or rather a tunnel, which will be utilised for discharging a portion of the Seine, below Paris.

The plan for the rebuilding of the École de Medicine is now ready to be presented to the Municipal Council of Paris. When all the works are completed the total surface covered will be 8,000 square yards; it does not now exceed 3,000. The expense will be 4,300,000 francs.

AN interesting article, by Mr. E. A. Barber, with some curious illustrations, on "The Rock Inscriptions of the Ancient Pueblos of the Colorado, Utah, New Mexico, and Arizona," will be found in the *American Naturalist* for December.

IN an article in the *Révue Scientifique* of January 6, M. H. Le Chatelier shows that there is no geological evidence for the existence of a great inland sea in North Africa, though there was probably in the district of the Tunisian Chotts, at one time, a small isolated salt lake. All the phenomena of the region of the Chotts and of the Sahara may be explained by the action of existing forces, which might at some future time cause a thin layer of salt water to reaccumulate over a small extent of surface.

WITH reference to our note (NATURE, vol. xv. p. 167) on Mr. Allen's work on the North American Bisons, which we stated was issued by the University Press, Cambridge, U.S., we are informed that this "University Press" has no relation with the University. It is simply a name denoting its position *near* the University grounds to distinguish it from another large printing establishment known as the "Riverside Press," also at Cambridge. The memoir noticed formed a part of the "Memoirs" issued by the "Museum of Comparative Zoology," which have taken the place of the former "Illustrated Catalogues," the title having been changed so as to enlarge the scope of the 4to. publications of the old numbers of the Catalogue collected into volumes to form the first volumes of the Memoirs.

ON December 20, the Bremer *Verein für die deutsche Nordpolfahrt*, changed its name to that of *Bremer geographische Gesellschaft*. The question of Polar exploration has assumed such dimensions that a private society cannot hope to accomplish much unaided in this direction. The society will henceforth devote its energies to the solution of geographical problems in other parts of the world. Its occasional communications are also to be replaced by a regular periodical appearing quarterly, under the editorial supervision of Dr. Moriz Lindeman. A special feature of the new society will consist in frequent courses of lectures from the most famous of recent explorers; Brehm, Güssfeldt, and Baron von Schleinitz, are announced as first on the list.

LATE letters from Sydney report the arrival of the Rev. G. Brown, who has been spending the last year in Polynesia, passing from one island to another in the mission brig *John Wesley*. Many interesting discoveries were made in the islands of New Britain and New Ireland. The inhabitants of both islands are cannibals, but indulge in the custom in order to show their complete mastery over their enemies, and not from a preference for human flesh. New Britain was coasted entirely and crossed several times. The interior is hilly, the loftiest point being 2,500 feet high. It is well populated, and the natives expressed the usual surprise at seeing white men for the first time. The tribe at Blanchi Bay informed the travellers of another tribe at some distance from the coast, who were provided with caudal appendages of an exceedingly remarkable character, and promised to obtain a specimen before the next visit of the brig. At another place, the wealthier families among the natives were accustomed to confine their daughters for several years before the attainment of puberty in tabooed houses, not allowing them to put foot upon the ground during the whole period. A superior tribe was encountered at Spacious Bay, with lighter complexions and straighter hair than their neighbours. Both sexes wore partial clothing. Large collections were brought back illustrating most fully the geology, the fauna, and the rich tropical flora of the islands.

M. CLEMENT GANNEAU, who has recently been in London to study the Semitic monuments in the British Museum, writes to the *Times* animadverting on the complete want of system in their arrangement. The Semitic remains are scattered among other collections in such a way as to make their examination a work of the greatest difficulty, whereas were they properly classified and arranged by themselves they would form a Semitic Room without a rival.

THE Geographical Society of St. Petersburg has received a telegram from Prjevalsky announcing that he has crossed the Thian Shan, and, on October 14, was fifty versts from Karashar. The country he was then in is a desert.

M. WADDINGTON, French Minister of Public Instruction, is busy fitting up a large pedagogical museum, which will be located in the hotel of the Ministry, and be open to the inspection of any scientific men interested in the progress of pedagogy.

THE first portion of the German *Jahresbericht über die Fortschritte der Chemie*, for 1875, containing 480 pages, about one-third of the complete work, has just been issued. General and physical chemistry receives 150 pages, inorganic chemistry, 80 pages, while the remainder of the number is devoted to organic chemistry, which will also occupy the greater portion of the second number. Prof. Fittica, of Marburg, assumes, with the volume for 1875, the chief editorial supervision, and is assisted by the following able corps:—K. Birnbaum, C. Böttinger, C. Hell, H. Klinger, A. Lauberheimer, E. Ludwig, A. Michaelis, A. Naumann, F. Nies, H. Solkowski, Z. H. Skraup, and K. Zöppritz. Complete sets of the *Jahresbericht* are difficult to obtain now as seven years' numbers are out of print. A perfect set from 1847 to the present date, with the two registers, costs from 500 to 600 marks in Germany. The editor requests from the authors of chemical articles separate copies of their communications in order to lighten the labour of classification and compilation.

WE have received vol. i. of the *Proceedings* of the Davenport (Iowa, U.S.) Academy of Natural Sciences. This Academy had a very small beginning in 1867, but is now in a flourishing condition. The volume contains the proceedings from 1867 to 1876, and includes some papers of real value, especially on mound exploration. The number of scientific societies in the U.S. issuing publications containing papers of genuine scientific importance is now large, and constantly increasing.

THE artificial lighting of rooms affects the human system, on the one hand, through the change produced in the composition of the air by gases of combustion, and on the other through rise of temperature. These influences have lately been examined by M. Erismann (*Zeitschrift für Biologie*). In a part of the laboratory 10 cubic metres' capacity, inclosed by wooden and glass walls, various materials were burnt eight hours, viz., stearine candles (six at a time), rape oil, petroleum, and ordinary gas, and the air was drawn off at different heights and analysed. The results do not pretend to absolute exactness, but a comparison of them is interesting. The tables first show that under all circumstances, and with all sorts of artifical lighting, the air of an inclosed space contains more carbonic acid and organic carbon-containing substances than in absence of such illumination; still, in these experiments the carbonic acid was never greater than 0·6 or 0·7 per 1,000, while the proportion of other carbon compounds was very variable, so that the amount of carbonic acid gives no exact criterion for the vitiation of the air. The CO_2 actually found in the air was only a very small fraction of that produced by the combustion; by far the greatest part must have been carried away by the natural ventilation. In comparing the four materials, the proportion of CO_2 and other carbon compounds was reduced to a light strength of six normal candles. It appeared that the petroleum, with lamp of good construction, communicates to the atmosphere, not only less CO_2, but (what is much more important) fewer products of imperfect combustion than the other lighting materials; and, further, that stearine candles, with the same light-strength, vitiate the air most. As to temperature, that of the lower layers of air, up to a height of 1·5 metres, rose very little during the eight hours, about 2° to 3° on an average, while the upper layers increased considerably in temperature, especially just under the ceiling; this increase, in the case of ordinary gas, rape oil, and petroleum, was 10·5° to 10·8°, in that of candles only 4°. If, however, we take into account the photometric light-effect of the flames during the experiment, it is found that, with equal light-strength, rape oil and gas raise the temperature considerably more than petroleum, and the action of the latter, indeed, came to about that of the candles.

THE additions to the Zoological Gardens during the past week include an American Black Bear (*Ursus americanus*) from North America, presented by Mr. W. Stead; a Common Partridge (*Perdix cinerea*), European, presented by Mr. H. Laver; a Razor-bill (*Alca torda*), European, presented by Mr. W. Thompson; two Common Swans (*Cygnus olor*), a Common Cross-bill (*Loxia curvirostra*), European, purchased.

SOCIETIES AND ACADEMIES

LONDON

Zoological Society, January 2.—Prof. Newton, F.R.S., vice-president, in the chair.—Prof. Newton exhibited and made remarks on a specimen of a variety of the guillemot (*Alca troile*) with yellow bill and legs, which had been lately shot by Mr. J. M. Pike on the south coast of England.—Prof. Garrod, F.R.S., read a paper on the osteology and visceral anatomy of the Ruminantia, in which many facts concerning the anatomy of the Cervidæ and the Cavicornia were brought forward, especially with reference to the shape of the liver and the structure of the generative organs in these animals. Among the most important of these was the observation that the uterine mucous membrane of the musk-deer (*Moschus moschiferus*) presents no indications of the presence of cotyledons, the contrary being the case in all other ruminants. Prof. Garrod likewise made a suggestion as to a proposed method of expressing the relations of species by means of formulæ.—A paper by Messrs. Sclater and Salvin was read containing the descriptions of eight new species of South American birds, namely (1), *Euphonia finschi*; (2), *Pheuticus crissalis*; (3), *Octhœca leucometopa*; (4), *Octhœca arenacea*; (5), *Chloronerpes dignus*; (6), *Celeus subflavus*; (7), *Chamæpelia buckleyi*; (8), *Crax erythrognatha*.—Mr. R. Bowdler Sharpe read a paper on some new species of warblers from Madagascar, which had been recently added to the collection in the British Museum, and were proposed to be called *Apalis cerviniventris*, *Bæocerca flaviventris*, and *Dromæocercus brunneus*, the last-named being a new genus, from Madagascar.—A communication was read from Mr. G. S. Brady, containing notes on fresh-water mites which had been obtained from lakes and ponds in England and Ireland.

Royal Microscopical Society, January 3.—Charles Brooke, F.R.S., vice-president, in the chair.—Dr. Wallich read a paper on the development, reproduction, and surface markings of diatoms, illustrating the subject by drawings.—An interesting paper was read by Mr. Stephenson descriptive of some very curious diffraction experiments, by Prof. Abbe, from which it appears that the use of "defraction gratings" in connection with stops of various kinds placed above the back combination of the objective were competent to produce precisely the same appearances as were observed in certain well-known test objects.—Some mercury globules mounted in balsam were exhibited under the micro-polariscope, by Mr. Stephenson for Mr. Slack, producing some very curious and interesting optical effects.

Manchester

Literary and Philosophical Society, November 28, 1876.—Edward Schunck, F.R.S., vice-president, in the chair.—The Radiometer. Mr. Harry Grimshaw, F.C.S., communicated the following summary of an extract from the "Panorama of Science and Art," published by Nuttall, Fisher, and Dixon, 1813, 2 vols. :—"After alluding to Boerhaave's experiment on the influence of the 'burning glass' on the motion of the 'compass,' the extract goes on to describe a radiometer constructed by Mitchell, which seems to have been constructed as follows :—A thin plate of copper one inch square was attached to one end of a fine 'harpsichord' wire ten inches long. This was balanced on an agate suspension, and the little copper plate was counterpoised by a grain of shot at the other extremity of the wire. As a result of experiments with the instrument, it was found that the influence of the rays of the sun focussed by a concave mirror two feet in diameter, caused a revolution of one-millionth of an inch in a second. The instrument was protected by some sort of glass shade. The same motion was produced in a vacuum."—Note on a manganese ore from New South Wales, and on a specimen of native silver from New Zealand, by M. M. Pattison Muir, F.R.S.E.

December 12, 1876.—E. W. Binney, F.R.S., president, in the chair.—The lowest amounts of atmospheric pressure during the last sixteen years as observed by Thomas Mackereth, F.R.A.S., F.M.S.—On a mineral water from Humphrey Head, near Grangeover-Sands, North Lancashire, by Joseph Barnes and Harry Grimshaw, F.C.S.—On ternary differential equations, by Sir James Cockle, F.R.S., Corresponding Member of the Society.

December 26, 1876.—E. W. Binney, F.R.S., president, in the chair.—Notice of the "Almanacke for XII Yere," printed by Wynkyn de Worde in 1508, by William E. A. Axon, M.R.S.L.—A notice of some organic remains from the Manx schists, by E. W. Binney, F.R.S., president.—On changes in the rates of mortality from different diseases during the twenty years 1854-73, by Joseph Baxendell, F.R.A.S.

Paris

Academy of Sciences, December 27, 1876.—Vice-Admiral Paris in the chair.—The following papers were read :—On the analysis of pyrogenic gases, by M. Berthelot.—On some derivatives of dialdol, by M. Wurtz.—Note by M. Chevreul on his more recent works. One is a *résumé* of the history of matter from the atomists and Greek Academicians down to Lavoisier. Another relates to experiments meant to show the difference of *absolute* black from *material* black.—On the secular displacements of the orbit of the eighth satellite of Saturn (Japhet), by M. Tisserand.—Researches on the velocity of the wind, made at the observatory of the Roman College, by P. Secchi. He gives a table of observations from 1862 to 1876, with Robinson's anemometer and a meteorograph. The general daily mean for the whole year is 197·5 km. It differs little from month to month, but the horary distribution is very different in the summer and the winter months. The velocity is greatest in March, least in September. But P. Secchi does not take his figures as representing the absolute velocity of wind in the country, as the College is in a low part of the city; observations on Monte Cavo will be better. He adds tables of mean hourly velocity in the different months.—On the project of an irrigation canal from the Rhone, by M. de Lesseps. The canal (schemed by M. Dumont) is estimated to cost 110 million francs; the irrigable surface (in five departments) might produce annually 450,000 tons of hay and support at least 100,000 additional head of large cattle. The scheme would also permit of submersion of the vines. It could be completed in four years.—M. Faye presented the *Annuaire du Bureau des Longitudes* for 1877, and noted improvements in it.—New measurement of the meridian of France, by M. Perrier. The operations now extend, in a continuous system, from the frontier of the Pyrenees to the Department of Loiret; there are thirty-nine stations.—On the absorbent power of wood charcoal for sulphide of carbon, and on the employment of sulphocarbonic charcoal for the destruction of phylloxera, by M. Laureau. M. Kvassery announced that the vines of Hungary are greatly threatened by Phylloxera.—Study on the reduction of a system of forces, of constant amount and direction, acting on determinate points of a solid body, when this body changes its orientation in space, by M. Darboux.—New theorems in higher arithmetic, by M. Lucas.—Enumeration of various theorems on numbers, by M. Proth.—Third note on the theory of the radiometer, by Mr. Crookes.—Researches on the coefficient of capillary flow, by M. Guerout. This coefficient is found to be smaller, in the same series, the more of carbon the substances contain. The author proved this before for monoatomic alcohols and homologous derivatives of benzine; it is here extended to fatty acids and ethers from the same alcohol, and ethers formed by union of the same organic acid with different alcohols of the fatty series. The coefficient for ethers is much higher than that of the alcohols or acids producing them; the introduction of an organic radical into the molecule of an alcohol raises its fluidity considerably. The determination of this coefficient establishes a sort of classification among isomerous bodies.—Practical study on gluten and on its determination in the dry state, by M. Lailler.—Researches on the physiological properties and the mode of elimination of bromhydric ether, by M. Rabuteau. This agent has properties intermediate between those of chloroform, bromoform, and ether.—Formation of the heart in the chicken, by M. Dareste.—On a *Balænoptera borealis* caught at Biarritz in 1874, by M. Fischer. This is the rarest of European species; only five examples have been known.—On a new globular state of quartz entirely crystallised in only one crystallographic direction, by M. Michel Levy. It is probable that the silica of this globular quartz was isolated in the paste before the end of the movement of effusion which produced the fluidality. The example furnishes a new combination of the colloid and crystalline states of silica.—Note on organic powders of the air, by M. Marié-Davy. The meteorological observatory of Montsouris has been charged by the Municipal Council of Paris to make a regular study of the dust of the air, the ground, and the water in various quarters of Paris, commencing with the new year. The author describes some preliminary observations relating to a recent epidemic.—On a maximum of falling stars, already indicated, in the month of December, by M. Chapelas.

FERMENTATION[1]

II.

Études sur la Bière. Par M. L. Pasteur. (Paris: Gauthier-Villars.)

WHAT is fermentation? Such is the important question of which we have now to seek the solution. It is necessarily impossible within the scope of a brief article to enter into an examination of the numerous theories propounded, yet a few words of explanation are needed in order that we may the more clearly understand what it is that Pasteur has done, and what is the real bearing of his answer to the question not only on fermentation, but on many a disease which flesh is heir to.

According to Willis and Stahl, to whom we are indebted for the first philosophical attempt at explanation, fermentation was due to a peculiar motion communicated from a decaying body to another substance, by which a similar degrading action was set up, so that complex molecules became less complex. This idea was subsequently taken up and developed by Gay-Lussac, Liebig, and others, who maintained that the decomposition of albuminous bodies produced the molecular disturbance by which sugar was broken up into alcohol and carbonic acid. Thus the molecular disturbance produced by decay of nitrogenous matter in a fitting liquid gave rise to lactic and butyric acids and other products.

The contact theory of Berzelius and Mitscherlich belonged to a period in the history of chemistry when catalysis was constantly employed to explain the unknown, and need not here be further alluded to.

Cagniard de Latour, in 1837, first proved that yeast is composed of living cells; this was confirmed by the almost contemporaneous observations of Schwann and Kützing, and subsequently by Turpin and others. The subject, however, remained in much obscurity until Pasteur commenced his investigations on the nature of ferments; these have been carried on for a period of twenty years, the results obtained being communicated to the French Academy in 1862 and subsequent years and are now, in so far as they concern the brewer, summed up in the important work before us. The theory of molecular disturbance produced by putrefaction, so energetically maintained by Liebig, may be considered vanquished on all points. M. Pasteur, from his researches, has proved incontestably the two following propositions:—

1. *Every diseased alteration in the quality of beer coincides with the development of microscopic organisms foreign to the nature of beer, properly so called.*

2. *The absence of alteration of beer wort and of beer coincides with the absence of foreign organisms.*

The first proposition M. Pasteur has amply proved from hundreds of examinations of beer undergoing diseased action; in no one case did he find the sediment of such beer to consist solely of the globular or ovoid alcoholic yeast cells, but of a more or less intermixture with the various ferments of disease already described by him with great minuteness in his "Études sur le Vin." His second proposition is a necessary corollary of the first.

We cannot do better than follow our author in some of his researches by which he has demonstrated the truth of these propositions. M. Pasteur, by boiling animal and vegetable infusions—it is not necessary in all cases to use so high a temperature—and then, by cooling them under rigid precautions against the introduction of germs from the air, has shown that they are then unacted upon by oxygen, at least that no putrefaction or fermentation ensues.

The temperature to which a liquid must be heated in order to ensure against subsequent decomposition varies with its nature. Thus while 50° C. is sufficient to destroy the germs in vinegar, malt infusion must be heated to 90° C., and milk to 110° C., and others require even higher temperatures. Blood and urine heated in Pasteur's flasks and cooled under conditions precluding the entrance of germs from the air undergo no alteration even when kept for weeks at a temperature of 20° C. in contact with pure air. Mere oxidation therefore is not the cause of fermentation and putrescence. It is unnecessary to refer to the exceptions taken by many experimentalists to Pasteur's conclusions, the great experimental skill required and the rigid precautions to be taken to secure success amply explain why others less habile than Pasteur have obtained conflicting evidence. Two of the ablest of his opponents, Doctors Brefeld and Traube, have recently retracted their previous objections to Pasteur's results, and now unhesitatingly adopt his views on Fermentation. Allusion has already been made to the fact that the brewer occasionally, and the wine grower invariably, leaves the saccharine liquid to spontaneous fermentation; it is many years since Pasteur first demonstrated that the dust on the skin of the grape contained the small organisms necessary for vinous fermentation, and that when these were destroyed or removed no fermentation took place. Thus the juice heated in a Pasteur flask with the usual precautions against the admission of germ-laden air did not undergo fermentation when freely exposed to germ-free air, but did so readily when a portion of the dust of the skin was added. If this dust, however, was removed by a few drops of water and then boiled previously to being added to the must no fermentation took place. Hence the dust on the skin contained the ferments, and M. Pasteur has demonstrated their nature and their distinguishing features.

In the case of boiling beer wort there are necessarily no living organisms, and therefore, as Pasteur has shown, there is no change when the wort is allowed to cool in a vessel to which only pure air has access. If, however, the cooled wort be exposed to air, ferments of various kinds, *e.g.*, *Saccharomyces cerevisiæ* (though rarely), *Sacchoromyces pastorianus*, and *apiculatus*, and other alcoholic ferments, fall into the liquid; at the same time, however, attended by more or less of the lactic and butyric ferments and other organisms of disease. In a brewery where other fermentations are proceeding, doubtless the number of alcoholic ferments will be greater and the injurious bacteria less than in other localities; still in any case the beer when finished must be very inferior, owing to the large quantities of acetic, lactic, and butyric acids, and other products of putrefactive change. M. Pasteur, having satisfactorily demonstrated that alcoholic fermentation was due to the action of certain organisms living and reproducing in a saccharine liquid, the question arose whether the common *Penicillium glaucus* and the *Aspergillus glaucus* could be transformed into the true alcoholic ferments of beer or of wine, and the still wider question of the conversion of one ferment into another; a question of vital importance to the brewer, since, if this theory of the conversion of one kind of ferment into another were proved to be true, the hope of obtaining greater power over the results of his process would be dashed to the ground, or at any rate such power would only be obtained in the distant future. In his researches upon this question, M. Pasteur availed himself of the liquid proposed by his pupil, M. Raulin (p. 89), *e.g* :—

Tartaric acid	4	,,
Nitrate of ammonia	4	,,
Phosphate of ammonia ...	0·6	,,

We must refer the reader to M. Pasteur's book for the full directions of procedure and the precautions to be taken in order to avoid the introduction of mixed organisms. No one can read this portion of his work without being greatly impressed by the author's wonderful ability in detecting and overcoming difficulties and thereby removing sources of error which have led so many to erroneous conclusions. We may briefly sum up this part of his work by stating that in no case where such necessary precautions were taken did he ever find that the penicillium changed to alcoholic yeast or to a mycoderma, or that yeast gave rise to vibrios, or that mycoderma aceti became yeast. M. Pasteur himself at one time thought he had detected the conversion of the mycoderma vini into a true alcoholic ferment; in this, however, he now finds he was in error, and that more rigorous precautions fail to support his original supposition.

In his experiments with mycoderma aceti and mycoderma vini carried out with his usual marvellous ingenuity and attention to details, he has shown that these organisms in contact with the air burn up the sugar of the liquid upon which they rest; and so far from alcohol being produced in quantities that may be detected, the mycoderma vini completely burns up any alcohol previously existing in the liquid. When submerged in the liquid, though life is far less active, they continue to exist for a time, undergoing structural changes, obtaining the necessary oxygen from the sugar, and producing alcohol, as in the case of the penicillium glaucus and aspergillus glaucus under similar conditions of submersion. We must admit, with Pasteur, that the production of alcohol and carbonic acid from sugar, in other words, alcoholic fermentation, is a chemical act attending the life of cells the moment they are removed from the influence of free oxygen, and are submerged in a saccharine liquid capable of yielding oxygen and heat by its decomposition. This alcohol-producing character becomes, therefore, not the isolated property of this or that organism, but a general function of a living cell, when removed from the air and compelled to obtain the necessary oxygen by the decomposition of its food. The duration of life and the production of alcohol will vary with the power of the cell to reproduce its kind under these submerged conditions. I have already referred to the production of alcohol and carbonic acid when growing malt is placed in an air-tight vessel. Under such circumstances alcohol and a large amount of carbonic acid are for a long time produced, ultimately the moist mass becomes increasingly acid, the production of alcohol ceasing and acetic and other acids being formed attended with a strong etherial odour. When first noticed by the writer in the year 1873 he was unaware of M. Pasteur's previous conclusions as to the action of vegetable cells. Messrs. Lechartier and Bellamy in 1874 published their valuable researches, upon which they had been engaged for some time, and they proved incontestably that the cells of fruits possessed the power, when removed from free oxygen, of obtaining this gas by the decomposition of sugar; alcohol and carbonic acid gas being produced, though not in the ratio found in true alcoholic fermentation. We thus learn from our author's researches, amply confirmed by those of Lechartier and Bellamy, that active living cells, when removed from the influence of free oxygen, and when placed under conditions where they must obtain it from saccharine materials, for a time continue to exist, producing alcohol and carbonic acid. Those, such as the cells of fruits and grain, which cannot reproduce under these conditions, soon die, and the amount of alcohol produced is but small; on the other hand those cells which can reproduce by germination become true ferments, and their action only ceases when the original reproductive energy due to their previous aërial condition also ceases. Thus when the *mucor racemosus* was submerged in a saccharine liquid it was found that the alcoholic fermentation was at first active and then finally ceased, the cells being deformed in contour, full of granulations, and to all appearance dead. The introduction of a little pure air, however, reinvigorated the apparently dead organism, and again—for a time—alcoholic fermentation was produced. Free oxygen therefore endows these simple cell-plants with an energy which enables them for a time, longer or shorter, to exist without it by obtaining the necessary oxygen from their food. I have said *for a time*, because the mucor racemosus, or the mycoderma submerged in a liquid soon lose their activity and cease to act, the true yeast ferments under the same conditions being enabled for a much longer period to reproduce and carry on their vital functions; even with these, however, Pasteur has proved the necessity of periodical aëration so as again to place them under their normal aërial condition, a fact long known to those English brewers who employ the method of *rousing* to stimulate the activity of the yeast. Pasteur's investigations on fermentation have convincingly proved—at least to most minds—the intenability of a *peculiar motion* and also of *spontaneous generation* as being the true cause of these interesting phenomena.

In addition to a continued life without free oxygen which the yeast cell manifests, there is another feature—exceptional in character—which it possesses, and that is, that its growth is not commensurate with the sugar decomposed. For a given weight of yeast formed one may have ten, twenty, or one hundred times its weight of sugar decomposed. It may be of interest to quote here two experiments—out of many—bearing on this question and also on the influence of dissolved oxygen in a saccharine liquid. M. Pasteur took two flasks partially filled with a liquid containing in each case 150 grammes of sugar; the one (*a*) was almost completely deprived of air, the other (*b*) contained air. A mere trace of yeast (species, *Saccharomyces pastorianus*) was added to each. The fermentation in *a* was sluggish, and after nineteen days, when the experiment was closed, there was still a slight evolution of carbonic acid gas; in *b* the fermentation was active, and ceased entirely on the ninth day. The weight of yeast formed was determined in both cases, as also that of the sugar left undecomposed; these were the results:—

a.	Weight of yeast formed	1·368 grammes.
	Sugar undecomposed	4·600 „
b.	Weight of yeast formed	1·970 „
	Sugar undecomposed	*nil.*

In *b*, therefore, though the liquid was far from being saturated with air, the decomposition of the sugar was completed in eight days, whereas in *a*, even at the end of nineteen days, there was still some sugar left. The weight of yeast formed was as 1 to 76 of sugar decomposed in *b*, and only as 1 to 89 in *a*. In another experiment on a sugar solution completely deprived of air, the whole of the sugar was not decomposed even at the end of three months, the yeast produced was deformed in appearance, and the ratio of yeast to alcohol produced was as 1 to 176. Reversing the experiment so as to obtain a thorough and constant saturation of the liquid with air, the ratio of yeast formed to the alcohol was as high as 1 to 4. In this latter case the yeast acted more as a mycoderm or as a mould than as a true ferment. We may sum up the bearing of the facts elucidated by Pasteur, by the statement that, within given limits defined in Pasteur's experiments, *the production of yeast is directly, and that of alcohol inversely, as the consumption of free oxygen.*

M. Pasteur having demonstrated that the alterations in the yeast, in the wort, and in the beer, are due to the action of microscopic organisms other than the true yeast cells, and that these ferments of disease are killed at a high temperature, it follows that if a boiling wort be cooled under conditions which preclude the entrance of these germs, and if fermented with pure yeast, a beer will be obtained which, so long as not exposed to germ-laden air, must remain unchanged for an indefinite time. M. Pasteur has conferred an additional favour on the practical man by designing an apparatus by which these conditions may be secured, and has carried on his process of fermentation on a large experimental scale in several French breweries with much success so far as flavour and soundness of product are concerned. The general adoption of new and costly appliances must necessarily be slow. Nor is it essential that his suggestions should be in all cases carried out in their entirety. The intelligent brewer who thoroughly masters the key to sound and unsound fermentation will be enabled to secure the one and avoid the other without replacing costly appliances by others vastly more so. To do this, however, the microscope must be in daily use in order to cultivate a purer and purer yeast crop, and his technical processes of skimming and cleansing must be more and more directed by this invaluable instrument. The selection and preservation of yeast, the cultivation of it and the gradual elimination of diseased ferments will henceforth be the object of well-guided efforts, and not of mere chance, as heretofore. The technical reader will do well to read and re-read the work before us; as he becomes master of its method of investigation and of the results obtained, so will he master many of the difficulties of his art.

Some suggestions are given (p. 224, *et seq.*) on the purification of yeast of interest to the brewer as well as to the experimentalist. It would lengthen this notice too much to give the details of the process; it will suffice here to state that the author recommends the use of a weak solution of sugar rendered slightly acid with tartaric acid. In some cases he employs in addition a trace of carbolic acid. Such a liquid destroys some true yeast; it is, however, far more injurious to the ferments of disease. It should not be forgotten that aeration, while injurious to most ferments of disease (mycoderma vini and aceti, of course, excepted), is a great stimulant to the Saccharomyces; hence this method may be adopted either alone or in conjunction with others suggested by him. Those interested in this matter, and especially the brewer, will do well to study carefully the work itself, they will find on this subject, as well as on many others, not alluded to here, much invaluable and suggestive information.

In concluding our brief examination of Pasteur's biological researches on fermentation, a few words on the products formed will not be out of place.

Numerous attempts have from time to time been made to express by a chemical equation the decomposition of glucose sugar by the yeast cell. Until the discovery of succinic acid by Schmidt, and of glycerine by Pasteur, the attempts made were far from being satisfactory. According to Pasteur 100 parts of cane-sugar corresponding to 105·26 parts of grape-sugar give when fermented—

Alcohol	51·11
Carbonic acid	49·42
Succinic acid	0·67
Glycerin	3·06
Matters united with ferments	1·00
	105·26

Therefore ninety-five parts of cane-sugar are broken up into carbonic acid and alcohol, one part is assimilated by the yeast, and four parts are converted into succinic acid and glycerin.

Monoyer has proposed the following equation to represent the decomposition of these four parts of sugar, *e.g.*,

$$\underset{\text{Hydrated cane-sugar.}}{4(C_{12}H_{24}O_{12})} + \underset{\text{Water.}}{6H_2O} = \underset{\text{Succinic acid.}}{2(C_4H_6O_4)} + \underset{\text{Glycerin.}}{12(C_3H_8O_3)}$$

$$+ \underset{\text{Carbonic acid.}}{4CO_2} + O_2,$$

the liberated oxygen supporting the life of the plant. It is impossible at present, however, to formulate the reactions which occur, because they vary according to the temperature, pressure, species of yeast employed, and to the nature of the saccharine liquid. M. Pasteur himself has pointed out that the proportions of succinic acid and glycerin vary in different experiments.

Mr. Horace Brown in some admirable and suggestive experiments on the influence of pressure on the products of fermentation (*Journ. Chem. Soc.*, 1872, p. 570), has shown that in alcoholic fermentation in addition to carbonic acid there is always formed a small quantity of nitrogen, hydrogen, and a hydrocarbon of the marsh gas series; the nitrogen being evolved from the albuminous matter of the wort. By diminishing the pressure the amount of evolved hydrogen increased, and with this an increase in the amount of acetic acid and aldehyde. These products, though very small compared with the alcohol and carbonic acid, the chief resultants of ferment action are yet sufficient to account for the etherial odour of a fermenting tun. Pasteur had previously noticed the production of minute quantities of volatile acids. On electrolysing a weak aqueous solution of invert sugar, Brown obtained carbonic acid, hydrogen, and oxygen, and at the same time an appreciable quantity of aldehyde and acetic acid, together with a small quantity of formic acid. It may be that water is decomposed in fermentation in small quantities precisely as occurs in ordinary vegetation; though highly probable, we have, however, no definite facts in support of the assumption. Our present knowledge of the chemistry of fermentation is somewhat vague and general, and much remains to be done before we shall be enabled by purely physical means to decompose sugar so as to produce the results brought about by the yeast cell.

As we progress in knowledge, so does our power to imitate the products of life-action increase, and assuredly the time will arrive when alcohol will be produced by simple physical or chemical means. For many a year to come, however, we must continue to depend upon the wonderful organisms known as yeast. Their life history and action on liquids have been elucidated by the genius and patient toil of Pasteur, and he has enabled us to select such ferments as are required to produce the result desired, and hence we are no longer the sport of chance.

The brewer and wine-maker are not alone in the debt due to the illustrious Frenchman whose work we have briefly examined; we are all interested in the far wider field of germ action opened out by him, whereby many a disease of man hitherto as dark and unexplained as was fermentation, will be brought under the illuminating light of his teaching.

He who has thus shown us the key whereby we may open the locked-up secrets of nature may rest assured of the gratitude of his fellow-men, given with the greater earnestness and respectful sympathy from the knowledge that our guide has impaired health and sight in his labours for others.

France has given many a great name to the roll of fame, but none more noble or more worthily inscribed thereon than that of Pasteur. CHARLES GRAHAM

CAYLEY'S ELLIPTIC FUNCTIONS*

Elementary Treatise on Elliptic Functions. By Arthur Cayley. (Cambridge: Deighton, Bell, and Co.)

THIS is a book thoroughly worthy of the great name of its author. It is difficult to know which to admire most, the grasp of the subject, the extreme simplicity of its exposition, or the neatness of its notation. It will, we think, at once take its proper place as the leading text-book on the subject.

In regard to notation, it seems to us to be thoroughly good throughout, not only in respect of the adoption of Gudermann's suggestion of the very short forms sn, cn, dn, for the sine, cosine, and elliptic radical of the amplitude of the function of the first kind, but throughout. In particular, we note an important typographical simplification in the suppression of the common denominator in long series of fractional formulæ, the denominator being given once for all, and its existence in each separate formula merely indicated by the sign of division (÷). This is a simplification, some equivalent of which we ourselves, and probably most of those who have worked at elliptic functions, have used in our private papers; but it is a new thing, and a very good thing, to see it introduced in a systematic form in a printed book.

Another very useful feature belonging to mechanical arrangement is, that the first chapter contains a general outline of the whole theory, so that its perusal enables the reader to see at a glance the plan and intention of the work. He is thus enabled at once to bring intelligent attention to bear upon his reading, instead of being distracted by the wonder as to what it is all driving at.

The intention of the work is, firstly, the direct discussion and comparison of the three forms of elliptic integral, and of the doubly periodic functions which are regarded as the direct quantities of which these integrals are inverse functions. Then the auxiliary functions Z, H, and H are taken up in an elementary form, and after this the transformation of the elliptic functions, by division or multiplication of the primary integral, with the corresponding change of modulus and amplitude. These are very fully and clearly discussed. In particular, the connection between the transformation of the radical in the elliptic integrals, and the formulæ of multiplication, is clearly brought out. Legendre had left this as a very puzzling, although necessary, inference, which he scarcely stopped to discuss. After this comes a discussion of the q functions, with a further discussion of the functions H and H, and then some miscellaneous developments.

The work is strictly confined to elliptic functions and their auxiliaries. The more general theories of Abel and Boole find no place in it, nor is there any general discussion of single and double periodicity such as forms the foundation of the work of Messrs. Briot and Bouquet. There are but few examples of the computation of particular values of the elliptic functions, and no account of general methods of computation, either of isolated values, or of tables, or of the arithmetic connected with them; nor are ultra-elliptic functions touched upon. The geometrical applications or illustrations of the elliptic integrals and functions are but meagre, and no mechanical applications are given.

The arithmetical work is quite rightly omitted. That will find a much better place in the hand-book or introduction which will doubtless accompany or follow the great tables of elliptic functions now being printed for the British Association. There is, however, one point which we think it an omission to notice, and that is the solution of the addition equation by means of auxiliary angles. (See Legendre, "Traité des Fonctions Ell.," vol. i., p. 22; or Verhulst, § 19, p. 40.) It is no defect, again, that the mechanical applications are omitted. These are better studied as they arise, as a part of mechanics rather than of analysis. But as regards geometry, we think there has been done either too much or too little. For instance, we have the usual theory of the representation of the arcs of the ellipse and hyperbola by those functions, and we have a long disquisition on the geometrical representation of the elliptic integral of the first kind by an algebraic curve; while there is no mention of the late John Riddle's discovery, that the arcs of the curves by which circles on the sphere are represented in Mercator's projection are directly given by, and absolutely co-extensive with, the elliptic integrals of the first kind, the amplitude being simply the longitude on the sphere. We think this quite as simple and as important as the discussion of the lemniscata. If we are to go into geometry at all, it might be as well also to make some allusion to Dr. Booth's discussion of the spherical conics, and to Mr. Roberts's integration of the Cartesians.

Then, again, we have an account of Jacobi's geometrical theorem in its original form, depending upon a family of circles having the same radical axis, while the corresponding theorem, depending upon circles having two inverse points in common, given by Chasles (see his "Géometrie Supérieure," cap. xxxi., p. 533), which much more directly represents both amplitudes and moduli, is not mentioned explicitly, although it is involved in the geometrical exposition given of Landen's theorem.

We have also been unable to find any account of Jacobi's reduction of the integral of the third kind to the form—

$$\int d\phi . E\phi : \Delta\phi$$

The transformations of the functions are worked out with great completeness, the results being tabulated in some rather formidable-looking, but really very convenient, schedules. This part of the work is carried almost to an extreme.

On the whole the book is one of the most important contributions to mathematical literature which has appeared for a long time. It is well done, and covers ground that was previously but ill occupied. It is clearly printed, and the fact that the proof-sheets have been revised by Mr. J. W. L. Glaisher is a guarantee for the correctness of detail. C. W. MERRIFIELD

OUR BOOK SHELF

Instruction in Photography. By Capt. Abney, R.E., F.R.S., &c., Instructor in Chemistry and Photography at the School of Military Engineering, Chatham. Third Edition. (London: Piper and Carter, Gough Square, Fleet Street, E.C., 1876.)

WE are very glad to find that Capt. Abney did not carry out the intention which he mentions in the preface of not producing another edition of his well-known "Instruction in Photography." That the little volume is widely known and appreciated is shown by the fact of its having reached a third edition, and we can only say that it well deserves its success. A photographer of the author's well-known skill and repute could not fail to be able to instruct others in his art, but when in addition he has gained large experience by continued practical teaching in such a school as that at Chatham his lessons become additionally valuable.

Capt. Abney does not enter much into theory, though he gives very good and simple accounts, illustrated by chemical equations, of the principal changes occurring during the processes described. We observe that he announces the forthcoming publication of a "Photography" among Messrs. Longmans' Text-books of Science, in which he proposes to deal more fully with the theoretical part of the subject. We shall look forward to this with considerable interest; meanwhile, for practical instruction in the art this little book distances all competitors. R. J. F.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*]

Just Intonation

THE errors and oversights—in my paper in NATURE, (vol. xv. p. 159)—with which Mr. Chappell charges me, are imaginary. To make the matter clearer, the vibration numbers of a diatonic scale started from $\frac{3}{2}$ as a tonic are—

$$\frac{3}{2},\ \frac{27}{16},\ \frac{15}{8},\ 2,\ \frac{9}{4},\ \frac{5}{2},\ \frac{45}{16},\ 3.$$

In order to keep to the same part of the keyboard, let the last five notes be depressed one octave, and we get this series:—

$$1,\ \frac{9}{8},\ \frac{5}{4},\ \frac{45}{32},\ \frac{3}{2},\ \frac{27}{16},\ \frac{15}{8},\ 2,$$

where $\frac{3}{2}$ is the tonic, and 1 or 2 the subdominant. A similar explanation applies to the scale starting from $\frac{4}{3}$ as tonic. With respect to the "comma of Pythagoras," I am not aware of any "generally adopted miscalculation." *Who* was the real discoverer of that interval is a matter of no consequence; but in a system such as the Pythagorean, which was tuned by true fifths, it would have been not only a very natural but an essential inquiry, "What definite number of fifths corresponds with another number of octaves?" This, without at all necessitating the supposition of the existence among the Greeks of instruments of an immense range in octaves, would be but an easy arithmetical calculation resulting necessarily in the conclusion that there was no exact coincidence between fifths and octaves, but that twelve fifths differed by a very small quantity from seven octaves. This small difference is therefore very aptly termed the Pythagorean comma. Now in the equal temperament system twelve fifths just coincide with seven octaves, so that the despised comma of Pythagoras is really a measure of the error of the equal temperament fifth. In fact, putting P for the comma in question—

$$P = \left(\frac{3}{2}\right)^{12} 2^{-7} \therefore 2^{\frac{7}{12}} = \frac{3}{2} P^{-\frac{1}{12}}$$

so that if 2 N be the vibration number of the lower tone of an E T fifth, that of the upper tone will be $3 N P^{-\frac{1}{12}}$, which is in error by $3 N(1 - P^{-\frac{1}{12}})$ vibrations, giving rise to a number of

$$\text{Beats} = 6 N(1 - P^{-\frac{1}{12}})$$

per second in the E T fifth. Not, however, that it is necessary to allude to Pythagoras or seven octaves to get those beats.

The grounds upon which Mr. Chappell declines to accept 24, 27, 30, 32, 36, 40, 45, 48, as representing the vibration numbers of the diatonic scale are not very clear, certainly; and repudiating these, he can of course have no sympathy with Colin Brown's keyboard.

To revert shortly to this, the subject of my previous communication,—in his new and very interesting work on "Temperament," Mr. Bosanquet has given a description of Colin Brown's keyboard, but in so peculiar a manner that it is really difficult to recognise the instrument at all, and neither its elegance nor simplicity are brought out as I think they should be.

A. R. CLARKE

Ordnance Survey, Southampton, January 9

South Polar Depression of the Barometer

I THINK it probable that on this subject Mr. Murphy's views and my own might have appeared more in harmony if we had neither of us expressed them with so much brevity. In my letter on Ocean Currents in NATURE, vol. xv. p. 157, I was incidentally led to speak of the barometric depression round the South as greater than that round the North Pole. In speaking of this superiority as "mainly due to superior evaporation in the water hemisphere generally," it did not occur to me that I could be misunderstood to mean that the excessive depression in high south latitudes is due to excessive evaporation taking place *within those latitudes*, an idea which, with Mr. Murphy, I regard as absurd.

The large areas of depression which the American meteorologists have termed the "Polar Cyclones" appear, on examination, to be themselves aggregates of those local depressions, or cyclones, which have penetrated either into the Arctic or Antarctic regions, and have there, either partially or wholly, coalesced. Local depressions starting from the edges of the great areas of excessive evaporation seem to be governed in their course by the distribution of relative humidity, and to be determined towards those districts in which precipitation is most in excess of evaporation. Consequently their forward development is, as a general rule—a rule to which there are in the northern hemisphere many important exceptions—somewhat towards the poles. As they advance between converging longitudes they commonly expand, and therefore become united, while the influence of the earth's rotation deflects their circulating currents further away from the points of lowest pressure. Mr. Murphy's view that the imperfection of the Arctic as compared with the Antarctic depression, is due to the amount of land in the northern hemisphere, and the local air-currents produced thereby, is not in opposition to my argument. Undoubtedly over Greenland the anticyclonic circulations predominate (except in the summer quarter) over the cyclonic. It is not improbable that somewhat analogous irregularities of pressure dependent on the distribution of land and sea may exist in high south latitudes. But I still think that it is to the middle latitudes of the two hemispheres that we must look in order to find the chief cause of the contrast between the Antarctic and Arctic depressions, for it is in the middle latitudes that the majority of the local depressions originate. In the southern hemisphere those latitudes are almost entirely occupied by surfaces in which evaporation is excessive. In the northern they are represented to a large extent by areas of relatively slight evaporation and predominant precipitation.

The correlation of wind and pressure-distribution is of a kind which can hardly be stated at the same time briefly and correctly. But if it is necessary to be concise, it seems more natural in every case to regard the distribution of pressure as the primary cause of the wind than to say "the cause of the depression round the Pole is the centrifugal force of the west winds."

Lutterworth, January 9 W. CLEMENT LEY

Sense of Hearing, &c., in Birds and Insects

MR. ROMANES (NATURE, vol. xv., p. 177) is not quite correct in supposing that the Death's Head is the only species of *Lepidoptera* known to "stridulate." Possibly the phenomenon is far more general than is commonly believed, although only few instances of its occurrence have been observed. In the current number of the *Entomologist's Monthly Magazine*, Mr. Swinton details the method in which a sound is believed to be produced by *Vanessa io* and *V. urticæ*, viz., by friction of a nervure of the hind-wings against a "filed" nervure in the fore-wings. *Chelonia pudica*, one of the tiger-moths, has long been known to produce a sound (*cf.* Solier, *Annales Soc. Entomol. de France*, 1837). In 1864, Guenée (*Ann. Soc. Fr.*, pp. 398–401) notices that the genus *Setina* possesses a tympaniform organ on each side of the breast, analogous to that found in the *Chelonia*, and in the same volume he is followed by Laboulbène, who gives an elaborate anatomical description of the organ in *Chelonia*, with figures (pl. 10). Another tiger-moth (*Euprepia matronula*) is said to stridulate (*cf.* Czerny, *Verhand. zool.-bot. Vereins in Wien*, 1859); and the existence of the phenomenon is (at least) suspected in members of other groups of *Lepidoptera*.

Without being able to prove it, I suspect that birds obtain a knowledge of the whereabouts of worms and subterranean larvæ by sight, and not by sound. In the case of the thrush, I think the excrement rejected to the surface guides the bird to the right spot. The starling during breeding-time feeds almost exclusively on the larvæ of *Tipula*. Here, again, I think it is sight, and not sound that aids the bird. True, in this case there is no rejected excrement on the surface, but there is something that may be equally significant to the eye of the bird, viz., the withered condition of the plants of grass, &c., telling a tale of the mischief that is going on below. Furthermore, is it not possible that if the movements of the larvæ below the surface cause sufficient *sound* to be heard above the surface, the movements of the bird should act as a warning, and cause the larva to cease feeding? The withered plant tells its own tale; if only flagging, but yet with some amount of vitality in it, the chances are that a larva is still at work at its roots; if entirely dead, then the larva has departed for another plant.

Confessedly in the case of the curlew and allied birds, the matter becomes very difficult of explanation, owing to the depth below the surface at which the food is found. But do these marine and other worms always keep at the depth to which the bird is obliged to penetrate in order to obtain them? *Solen* is believed to remain near the surface until warned that an enemy is near, when it descends with rapidity. The worm might also be ordinarily near the surface, and the slight movement thereon caused by its endeavours to bury itself deeper might result in its destruction. I throw this out as a suggestion, because it is hard to believe that sound produced by the movements of an annelid could be transmitted through nearly a foot of sand. There is yet another difficulty. In the case of the curlew the sound would have to travel nearly a foot *above* the surface before it reached the auditory organs of the bird.

Lewisham ROBERT M'LACHLAN

THE "CHALLENGER" COLLECTIONS

THE following "Preamble" to a list of observing stations, printed for the use of the naturalists engaged in preparing the account of the voyage, contains so much likely to interest naturalists generally that we think it useful to publish it in NATURE:—

The special object of the *Challenger* Exploring Expedition was to investigate the physical and biological conditions of the great ocean basins; and with this object in view, during an absence from England of three years and a half, and at intervals as nearly uniform as circumstances would permit, throughout a course of 68,890 miles, 362 observing stations were established.

The following list of these stations has been compiled for the use of those naturalists who have consented to assist in the working out of the scientific results of the expedition, with a view to their being published in an official account of the voyage. Interesting observations were made on land as opportunity occurred during the short periods of the *Challenger's* stay in port, and during her short visits to remote islands; but these observations were necessarily desultory and incomplete, and it has been decided to omit their consideration from the present work, and to publish such as may appear of sufficient value in the transactions of learned societies. The Official Report will thus consist strictly of an account of the additions which have been made to the knowledge of the physical and biological conditions of the ocean by the expedition.

At each station the following observations were made, so far as circumstances would permit. The position of the station having been ascertained—

1. The exact depth was determined.
2. A sample of the bottom averaging from 1 oz. to 1 lb. in weight was recovered by means of the sounding instrument, which was provided with a tube and disengaging weights.
3. A sample of the bottom water was procured for physical and chemical examination.
4. The bottom temperature was determined by a registering thermometer.
5. At most stations a fair sample of the bottom fauna was procured by means of the dredge or trawl.
6. At most stations the fauna of the surface and of intermediate depths was examined by the use of the tow-net variously adjusted.
7. At most stations a series of temperature observations were made at different depths from the surface to the bottom.
8. At many stations samples of sea-water were obtained from different depths.
9. In all cases atmospheric and other meteorological conditions were carefully observed and noted.

10. The surface current was determined as far as possible.

11. At a few stations an attempt was made to ascertain the direction and rate of movement of water at different depths.

The numerical results of observations yielding such are now available in the logs, in the various reports of the Admiralty, and in the note-books and official journals of the naval and civilian scientific officers attached to the expedition.

The samples of the bottom procured by the sounding-instrument were carefully preserved in tubes or in stoppered bottles, either dry; or wet, with the addition of alcohol.

The samples of bottom and intermediate waters were determined as to their specific weight; in some samples the amount of carbonic acid, and in others the amount of chlorine, was determined; in others the contained gases were boiled out and sealed in tubes for future examination; and a large number of samples were reserved in stoppered bottles for analysis

The mud and minerals and inorganic concretions brought up by the dredge or trawl were preserved in large quantity in boxes or jars for examination and analysis.

The collection of invertebrate animals is of great extent; and from most of the species being undescribed, and from the great peculiarity of the distribution of the fauna of the deep sea, it will perhaps yield the most generally interesting results.

The invertebrate animals from the deep-sea stations were, with few exceptions, placed in jars of rectified spirit, closed with stoppers smeared with a mixture of tallow and wax, covered over with bladder, and the tops painted with a black varnish. The animals of different groups were in many cases roughly selected at each dredging, and put into different jars; but frequently, in order to save jars and spirit, it was necessary to put the whole result of one dredging into one or two jars, the animals of all groups mixed. Each jar was marked outside with the locality and the number of the station; and the station number, written with a black pencil on a slip of parchment, was placed *within* each jar. The collection on its arrival in this country was thus arranged geographically. It came home in most excellent order.

To insure accuracy so far as possible, the observing stations have been numbered from 1 to 354, and a number corresponding to the station is on every sample of every description, and on every record of the result of observations for every station; and the same number is carried through the whole series of journals and other books kept by the members of the Civilian Scientific Staff.

It is now our object, in preparing a scientific account of the voyage, to describe these investigations, and to give their results in detail; and to develop, as far as possible, the bearings of these results upon one another, and upon the broad problems of physical geography and hydrography.

For this purpose it is necessary that the various numerical results should be reduced and tabulated; that the samples of soundings should be examined chemically and microscopically; that the samples of water and of air should be analysed; and that the animals procured by the dredge should be most carefully catalogued as to localities, and the forms new to science described.

The data for the physical and chemical work are in few hands, and these chiefly at head-quarters. It is especially for the assistance of the naturalists dealing with the deep-sea fauna that these notes are drawn up.

Prof. Agassiz, Mr. Murray, and I have now gone over the whole of the collection of marine invertebrate animals in spirit; and we have separated the zoological groups from one another for each station, and re-arranged the collection in zoological order. Each jar, therefore, now contains animals of one group only (*e.g. Ophiurids* or *Alcyonarians*), to be described by one person. Each jar has within it a station number, which refers to the specimens which are loose in the jar; but in many cases, to save space, and to lessen the number of large jars, there are in the same jar several packets done up in muslin, each packet containing animals of the same zoological group from another station, and each packet having within it its own station number.

The jars will be placed in the hands of the naturalists who undertake the description of the different groups in their present condition; and in order to secure uniformity and the safety of the collection, they are requested—

1. To go carefully over the whole collection intrusted to them, and to select a first series, including all unique specimens and a sufficient number of specimens of those of which there are several duplicates, to illustrate their geographical distribution; and to associate with each species a particular number, by which number that species may be always referred to afterwards—at all events, until it has been described and named. This is the collection which is to be described and figured, and it is ultimately to be placed as a collection of types in the British Museum. It will usually be desirable, for the purposes of description and illustration, to put the specimens of the first series into rectified spirit in clear glass bottles; and I will arrange in each case how the bottles are to be provided and the expense defrayed. This collection must be retained by the describer until the description of the whole is finished.

2. To select at the same time a second set, consisting of a complete series of duplicates, numbered to correspond with the numbers attached to the first series species for species, and to pack them either in separate bottles or in packets in muslin, a number of packets together in one store bottle. This set to be returned to me for reference.

3. To pack up again all the duplicates from the different stations, each species from each locality either in a separate bottle or in a muslin packet, with the station number and the number corresponding with the type specimen of the species along with it. It will greatly facilitate matters if this general duplicate collection is returned to me along with the first series of duplicates, whenever the collection has been gone over, and the first series for description selected out.

4. For easy reference, each naturalist who undertakes the working out of a group will be provided with a large number of small vellum labels, marked thus:—

Ast.	(Asteridea.)
St	(Station.)

and he need simply enter, *with a dark pencil*, the number which he has associated with the particular species, and the number of the station where the specimens were found; and put the label *into* the bottle or the muslin bag, as the case may be.

Special arrangements must be made in every individual case as to publication, but it is the general intention that the account of the voyage shall be in a series of volumes quarto, of the size of the *Philosophical Transactions* of the Royal Society. It will probably consist of—

1. Two volumes, containing—(1) such a general account of the voyage, and such hydrographic details, illustrated by charts and sections, as may be necessary for the clear comprehension of the scientific observations; and (2) a full discussion of the general results of the voyage, physical and biological. To these volumes will be appended tables of the routine observations in meteorology, &c., made during the voyage.

2. A volume containing an account of the physical and chemical observations and investigations, with a special discussion thereon. To this volume will be appended tables of analysis, tables of specific gravities, reports on the microscopical examination of minerals, &c.

3. A series of volumes, probably not less than six in number, containing a detailed account of the fauna, and plates illustrating the undescribed or imperfectly known forms.

In case of plates being required, the space available for figures on each plate is not more than 11 by 8½ inches (= 28 by 12·5 centimetres). It is intended that the plates shall be, generally speaking, in lithograph; but if any form of engraving seem preferable in any case, a special arrangement may be made. Woodcuts will be given where required.

I undertake the editing of the work, and all manuscripts and proofs of plates are to be sent to me.

All packages and letters to be addressed—

Professor Sir Wyville Thomson, F.R.S.,
University,
Edinburgh.

and marked "*Challenger.*"

The intention at present is that the preparation of all the volumes shall go on simultaneously, and it is earnestly desired that the different parts may be done as speedily as is consistent with the utmost care and accuracy. Authors are invited to enter into any anatomical or other details which may be desirable for the full illustration of the groups in their hands; and their full consideration is particularly requested of all questions bearing upon geographical distribution, and upon the relation of the deep-sea fauna to the faunæ of the later geological periods.

Authors will be at full liberty to publish abstracts of the results of their work during its progress, in the proceedings of Scientific Societies; but such communications should be made through me or with my knowledge, and "by permission of the Lords Commissioners of the Treasury."

I am directed to report to Government and to furnish my accounts at certain intervals; and in order that I may be able to do so, authors are requested to report progress and to render accounts and vouchers for any expenses which they may have incurred, to me quarterly; on or before the 1st of March, of June, of September, and of December.

In the following list of stations—

1. The number is given by which each particular station is referred to throughout. The first eight stations, to which Roman numerals are attached, are to be considered in a certain sense preliminary; the regular series commences with Station 1 (*bis*) on the 15th of February, 1873, and is indicated by Arabic numbers up to 354.

2. The date is given.

3. The exact position of the ship at noon of the day on which the observations were made.

4. The depth in fathoms (= 6 English feet).

5. An abbreviation, as it is given on the chart, indicating the nature of the bottom:—

r. (rock) indicates hard ground, where nothing was brought up by the sounding instrument, there being at the same time evidence that the tube had reached the bottom.

m. (mud), a material varying in colour, but derived chiefly from the disintegration of the land.

gl. oz. (globigerina ooze), a white or greyish deposit formed in a great measure of the shells, entire or broken, of foraminifera belonging to the genera *Globigerina*, *Orbulina*, *Pulvinulina*, and *Hastigerina*, usually with a quantity of amorphous calcareous or earthy matter, and many coccoliths.

di. oz. (diatom ooze) indicates a deposit formed to a great extent of the frustules of diatoms which have sunk from the surface.

rad. oz. (radiolarian ooze) indicates a deposit composed mainly of the skeletons of Polycystina and other Radiolarians.

r. cl. (red clay) indicates a deposit, very widely extended in deep water, of red, reddish, or grey aluminous mud, such as would be produced by the decomposition of a felspathic mineral. This deposit varies considerably in character; it seems to be derived from several sources, but one of the most important of these appears to be the decomposition of pumice and other volcanic products. The "red clay" often contains concretionary nodules, consisting chiefly of the oxides of manganese and iron.

gr. oz. (grey ooze), and gr. m. (grey mud), usually indicate an intermediate condition between Globigerina ooze and red clay, or in some cases a fine-grained grey deposit, formed in deep water, chiefly of land *débris*.

The positions of the stations are shown on the accompanying chart. C. WYVILLE THOMSON

Edinburgh, January 2

PROF. AGASSIZ ON THE "CHALLENGER" COLLECTIONS

PROF. AGASSIZ, who has come to this country for the express purpose of examining the *Challenger* Collection, has kindly sent us the following notes on what he has already seen:—

I have seen a great many alcoholic collections of marine animals made by direction of different government expeditions, and in no case have I seen one in a better state of preservation, or where greater care had been taken to insure the accuracy of the locality. Those who work up the material will have the double advantage of working on admirably-preserved collections, and of being absolutely certain of the exact locality of their specimens. Sir Wyville Thomson has already called attention, in his Preliminary Reports to the Royal Society and his Lecture before the British Association at Glasgow, to many of the most interesting things collected, and he has also alluded to the amount of the material brought together. I may perhaps give a better idea of the magnitude of the collections by stating that if a single individual, having the knowledge of the eighteen or twenty specialists into whose hands the collections are to be placed, were to work them up, he would most certainly require from seventy to seventy-five years of hard work to bring out the results which the careful study of the different departments ought to yield.

We may assume that the work of the *Challenger* has probably accomplished for the depths of the ocean in general what the American and English expeditions of 1866–1869 did for the North Atlantic, for it certainly is remarkable how much these expeditions, working over a comparatively limited area, contributed to the knowledge of the deep-sea fauna, and how little of novelty has been added by the subsequent and more extended work of the *Challenger* over the same ground. Judging from these premises, we may fairly say that hereafter, while any new expedition will undoubtedly clear up many of the points left doubtful by the *Challenger*, and may carry out special lines of investigation only partly sketched out, yet we can hardly expect them to do more than fill out the grand outlines laid down by the great English expedition.

To attain the best possible results it is of the utmost importance that the collections brought home should be placed in the hands of specialists who are thorough masters of their respective departments. The scientific public will therefore hear with the greatest satisfaction that the Government has left the collections in the hands of Sir Wyville Thomson, who is to direct the publications until the whole of this invaluable material is thoroughly worked out.

REMARKS ON THE NEW MONOTREME FROM NEW GUINEA

A FEW weeks ago we announced to our readers the remarkable news of the existence of a mammal of the order Monotremata in New Guinea. The receipt of a separate copy of the description of this animal, just published by Dr. W. Peters and the Marquis G. Doria,[1] enable us to give a few more particulars of what must be universally regarded as one of the most important zoological discoveries of the period.

Mr. Bruijn, of Ternate, to whom science is indebted for our first acquaintance with this novelty, gives the following details of its discovery in a letter to the Italian naturalist, Dr. Beccari:—

"Two years running my native collectors have brought me word that, according to the Papuan mountaineers, there are a good many mammals in New Guinea, but that they are only hunted there when they are required for food. At first I did not place much confidence in these stories, because I know the little value of the reports of the hunters and the natives in general. Nevertheless, I have always told them to look carefully for mammals. The last time they set out I told them, in order to stimulate their zeal, that I knew that a certain animal existed in New Guinea of which I showed them a figure, and that I wished to have it at any price, hoping that in searching for it they would, perhaps, find other new or little-known species. The figure which I showed to Joseph and the other hunters was that of an *Echidna*.

"This year (1876) my men ascended a peak of the Arfaks called Mickirbo, and halted at a spot about the same height above the sea-level as Pjobieda. Here Saleh entered a hut where a piece of a skull of a mammal was offered to him, which he at once thought belonged to the animal which I required. He accepted it and forthwith commenced interrogating the Papuan who had given it to him. The latter told him that the skull belonged to an animal with four legs, with a tail, as large as a dog, and with long harsh fur; he added that these animals were not uncommon on Mount Arfak, and concealed themselves in small caves, and that the Papuans hunted them with dogs, being very fond of their flesh. The skull in question belonged to an animal that had been killed about a month before. Acting upon this information, Saleh set to work to hunt for this animal, but without success. It was only after he had descended from the mountains that a second skull was brought to him, which was still stinking from the fragments of rotten muscles attached to it."

One of these two crania reached the Museo Civico of Genoa, in November last, and constitutes the material upon which Messrs. Peters and Doria, who are engaged on a joint memoir upon the Mammals and Reptiles of New Guinea, have founded their *Tachyglossus*[2] *bruijnii*.

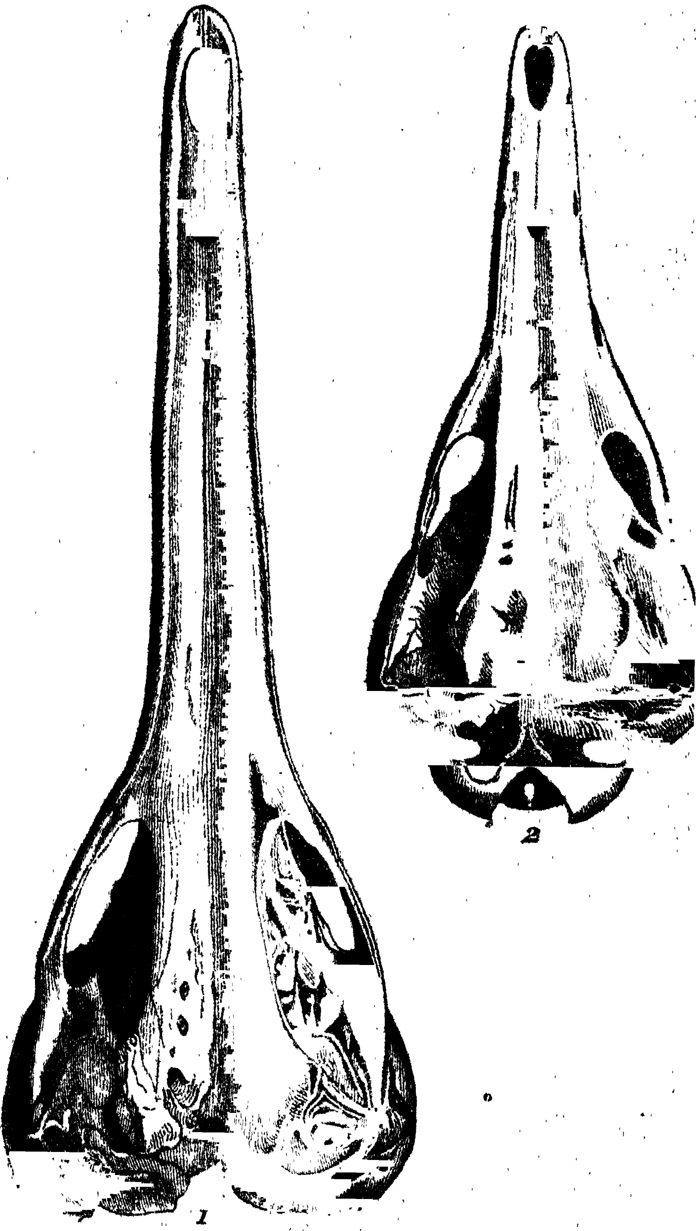

Fig. 1.—Skull of Tachyglossus of New Guinea. Fig. 2.—Skull of Tachyglossus of Australi

It will be observed that this skull, of which a figure is given herewith (Fig. 1), copied from that of Messrs. Peters and Doria, wants the greater part of its posterior portion, and also the lower jaw. But it is quite perfect enough to enable one to see at a glance that the species must be quite distinct from the Australian *Tachyglossus hystrix* and *T. setosus*. In the first place the size of the skull is much greater, and the rostrum of the new species is longer by one half, measuring in total length about 6·4 inches, instead of 4·2 inches, as in the Australian animal,[1] of which a skull is represented (Fig. 2) for comparison. Again, in the Papuan species, the rostrum is curved downwards throughout its length, which is not th case in the Australian forms. Other minor difference are pointed out by Messrs. Peters and Doria in thei excellent description, which we need not repeat here. I is quite sufficient to compare the outlines of the two skull together to convince oneself that the newly-discovere animal must belong to a much larger and quite distinct species, of which we trust it will not be long before perfect examples are received in Europe.

---

[1] W. Peters e G. Doria: "Descrizione di una nuova specie di Tachyglossus proveniente dalla Nuova Guinea settentrionale." Ann. Mus. Civ. di St. Nat. di Genova, vol. ix. (December 3, 1876)

[2] The "Spiny Ant-eater" of Australia is usually called *Echidna* in scientific nomenclature, but Messrs. Peters and Doria reject this term in favour of *Tachyglossus* of Illiger, because *Echidna* was previously applied by Foster in 1778 to a genus of fishes.

[1] It is not known to which of the two Australian species this skull belong but they are closely allied, and as regards size there is little if any differenc between them.

The significance of the discovery of a species of *Tachyglossus* in New Guinea will be appreciated when we consider that hitherto the Monotremes or Ornithodelphs, which, according to the most recent authorities, constitute not merely a distinct order, but even a separate sub-class of mammals, have been supposed to be at present exclusively restricted to Australia. The two only known genera of Monotremes are *Tachyglossus* (sive *Echidna*) and *Ornithorhynchus*. Of the latter the single known species is peculiar to South-Eastern Australia, of the former, the two species are found, one in South-Eastern Australia, and the other in Tasmania. The whole of the north and west of the Australian continent is, so far as we are at present informed, without any representative of this remarkable group. Looking at these facts, the discovery of a species of Monotreme in New Guinea becomes still more significant, and leads us to expect that when the mountain-ranges of Queensland have been further explored, some representative of the order may still be found lingering in this district, and uniting the newly-discovered area of distribution with that previously known.

Finally we may remark that the fundamental unity of the Papuan and Australian fauna was already sufficiently obvious by the existence amongst mammals of *Macropus* and amongst birds of such peculiar genera as *Orthonyx* and *Climacteris* in New Guinea. The discovery of *Tachyglossus bruijnii* is another confirmation of the correctness of this view, as regards zoology, though, as regards the flora of New Guinea, facts, we believe, point rather in another direction.

P. L. S.

ON THE TROPICAL FORESTS OF HAMPSHIRE[1]

II.

It has been mentioned that in some of the clays remains of leaves, fruits, and flowers are met with, and I will now proceed to tell you something about them. There are some enlarged drawings here on the wall which I should tell you are not all enlarged to equal scale, and there are trays of specimens on the table.

These leaves are found in various conditions of preservation. In most cases the impression only of the leaves in the clay is met with, but in some cases they are so well preserved that the actual substance has been retained although chemical changes have altered its composition, and it will peel off and blow away. In some of the clays the masses of leaves are so decayed that they cannot be recognised, and are not worth our collecting.

Where the preservation is good we can readily distinguish the various original textures of the leaves by comparing their general aspect and colour both among themselves and with existing forms. For instance, those which are thick, such as evergreens, thin, as convolvulus, hard, such as oak, or soft, such as lilac, or even velvety, such as the common phlox, can all be recognised. Their colours, in most of the beds, vary from buff to brown, but I need hardly tell you that in no case have we any of the green colouring of the leaves preserved. Whilst these various shades of dark buffs and browns are in many cases the result of chemical change that has taken place after the leaf was covered up, yet I believe that in many cases this change had occurred, at least partially, before the covering up, just as we saw a few weeks ago the changed colours of the fallen leaves of autumn.

In the darker clays the remains are black and completely carbonised; where this is so the finer venation is indistinct and the remains difficult to save, so that we may discard them unless the outline of the leaf is of unusual form. The darker browns, I take it, indicate hard and evergreen leaves; for instance, the laurel-like leaves are always of a deep colour, whilst both the thin and the succulent leaves are always of light colour, as in the leaves which we suppose to be fig, some species of smilax, &c.

No other colours have been met with with one remarkable exception; fragments of a reed-like aspect are found of a deep violet, staining the surrounding clay mauve for a considerable distance.

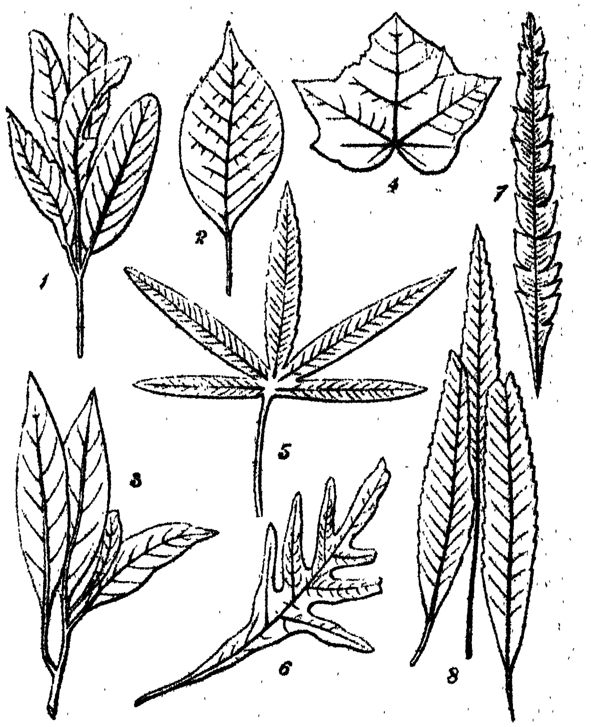

Fig. 4.—Leaves of Dicotyledons, from the Lower Bagshot Beds. 1 and 2, Fagus; 3, Laurus; 4, Acer; 5, Aralia (?); 6, Stenocarpus; 7, Dryandra; 8, Quercus.

I next call attention to the shapes of these leaves; the most cursory examination shows that the differences in shape are very great. Here are drawings of palmate leaves, leaves resembling in general shape the beech, the sub-tropical Dryandra, which, though unfamiliar, have been probably seen by most of you in the warmed houses at Kew; laurel-like leaves, a tropical kind of oak, maple, smilax, aralia, yew, palms, and a fern. These have been selected to show the great diversity in the shapes which existed.

Most people are familiar with the process of skeletonising leaves—that is, the removal of the green part, and the preservation of what is called the skeleton. I have here a large case of leaves so prepared by Mrs. J. E. Gardner, and which may be examined at the close of the lecture.

I would next draw attention to some leaves of trees which are well known as now growing in England. In these a continuation of the leaf-stalk can clearly be distinguished running through the leaf, which is commonly called the *mid-rib*. [The mid-ribs in two diagrams were coloured red.] Those running from the primary ribs are called *secondary* ribs (coloured blue). There are, again, running from these many smaller portions, which are called the network of the skeleton. In some, as, for example, the plane-tree, there are three primary ribs; in a few leaves there are more. In some, these principal ribs are very strong, and form prominent features; in others, as in the convolvulus, they are but slight. Some of these secondary ribs run straight to the margin, and in other cases they are curved. Again, in some they run right out to the extremity of the margin, as in the elm; and in others they are curved back, as in the fig. These are things to be noticed, which it will be seen are of consequence.

---

[1] Lecture in connection with the Loan Collection of Scientific Apparatus, given at the South Kensington Museum, December 2, 1876, by J. Starkie Gardner, F.G.S. Continued from p. 233.

I wish now to refer to the character of the margins of the leaves. Here is a drawing of a fig leaf in which a perfectly smooth margin will be observed; whilst the elm is saw-like, or *serrated*, as botanists call it. In the dryandra the margin is deeply notched, whilst in a strange-looking form (Stenocarpus) the edge is markedly lobed; in the case of some palmate leaves the edge is smooth, as in the passion-flower, or serrated, as in the fossil aralia. Those who have paid any attention to leaf form, have no doubt observed that leaves, even from the same plant, differ in some of these characters. This constitutes one of the greatest difficulties which presents itself to the botanist, in the endeavour to decide by comparisons to what plants the fossil remains probably belonged. Still, there are numbers of specimens with which we have to deal presenting forms so unmistakably alike that we are able to group them together; and even putting on one side many fossil forms about which we must feel considerable hesitation, there still remain a vast number about which we can feel little hesitation as to the value of the comparisons.

It is worth while to point out that when we compare these leaves with the existing flora and contrast in like manner the plants of the coal period with the existing vegetation, we see that there is a much closer resemblance between these plants and the present plants than there is in the case of coal plants. That is, that in these forms we have a nearer approach to the existing state of things than there was in the coal period, a matter which, in viewing the evolution of plant life, cannot be overlooked, whatever may be the value to be set on such evidence. Those who know anything of the plants of the coal period are aware that we find there gigantic forms of which we have only dwarf representatives at the present time. The principal of these forms are gigantic horse-tails or Equisitaceæ, great lycopods, as the Lepidodendron and Sigillaria, and tree-ferns, all very unlike the representatives of these groups now living. Here, however, the resemblances to the existing vegetation is close, not only in the arrangement of the ribs, but the size of the leaves, and also in those cases where we have groups of leaves joined by twigs, the method of attachment is similar.

To determine to what kind of plants each of these leaves belongs is a matter of considerable difficulty and requires an extensive knowledge of the plants now living on the earth. Although we have collections of growing plants from different parts of the world in various conservatories, such as at Kew, it is on the dried specimens brought home by travellers, or sent from abroad, that we mainly have to depend. How frequently leaves closely resembling each other but belonging to plants of widely different kinds are met with, the careful student of botany knows well. It requires a comparison by a skilled eye of the most minute details to arrive at conclusions on which any reliance may be placed.

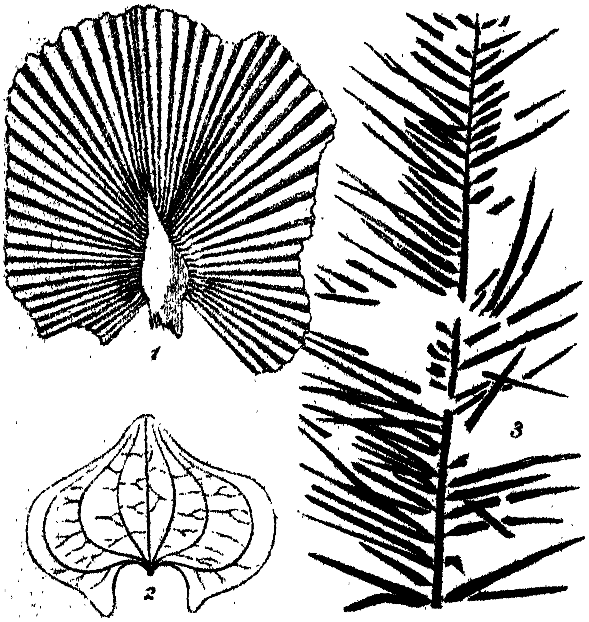
The work of comparison of this immense number of leaves is necessarily a work of considerable time, and is still in progress, but some conclusions have already been arrived at. I call your attention to a large group of growing plants, from the conservatory of Mrs. J. E. Gardner, which illustrate the kind of foliage existing in England in the Eocene time. Those who have paid attention to this subject will not doubt that these are palms; these are unmistakable ferns; botanists are agreed that this form is undoubtedly referable to the group to which *this* dryandra belongs; this may with almost certainty be referred to the beech tribe; this doubtless belongs to the same tribe as the pea; this is an aralia; this an acer or maple; this a laurel, and this a yew. Specimens of elm, acacia, chestnut, great aroids, as well as hundreds of other forms, have been obtained, some of the comparisons of which have already been determined, and some few are of forms which appear to have no living analogies whatever. There are also countless fruits, many of which can be recognised as like those now existing; a few flowers too have been met with. These fruits are of great assistance in telling us what plants were living at the time, as they are compared with greater certainty than the leaves can be.

I have mentioned the cabinets in the Loan Collection; close by is a cabinet which contains the collection made by Baron von Ettingshausen, and although time does not permit me to do more than allude to them, I would just mention that collections of an approximately similar geological age have been made from Switzerland, Italy, Greenland, and Austria, so that taking together all these localities we get a fair notion of what was the vegetation of the period which geologists call Eocene. You must remember geology is a study only of this century. Interest, at first small, spreads now over all Europe, and gradually records of past vegetations of different ages are being brought to light and compared.

I would say a word or two by way of explanation of the origin of the different colours of the sands and clays which have been mentioned. The yellows, buffs, and reds, which form the prevailing colours of the lower series, owe their origin to iron in various chemical conditions. The granite from which they were derived contains sufficient iron to account for iron being in solution in the streams by which they were deposited. The different colours of the different oxides of iron are here shown. The anhydrous sesquioxide is of a deep tinge: the hydrous sesquioxide gives a yellow colour. [A successful experiment was then made with a large glass jar of rain-water with dissolved grey granite held in suspension. To show the amount of iron present in the granite, a little ammonia was added, which changed it to a dark colour. The green oxide thus obtained would, on evaporation of the water, take another degree of oxygen and change to a bright red sesquioxide. This red oxide was produced in a second jar, and shown to be the same as the colouring matter of the red clays.] De la Beche, in his researches in theoretical geology, alludes to the fact that pipe-clays of similar colours are now being deposited in some of the lakes of North America.

Whilst some of the dark colouring of the darker clays is due to iron, that of some of the middle clays may be due to the fact that, whilst these beds were being deposited, the source of the stream was coming from a district farther north, cutting perhaps across the Somersetshire and Gloucestershire coal-field.

The question may perhaps have presented itself to your minds—how is it possible that the tropical forms of which we have spoken, such as the *palm*, *aroids*, *cactus*, &c., could have grown alongside of the apparently temperate forms, such as the *oak*, *elm*, *beech*, and others. Time does not allow that I should go at any length into the explanation of this; but I may just remind you that in the long geological record of the beds found in England, there are to the geologist unmistakable indications of many changes in climate. Further, astronomers, having calculated the path of the revolution of the earth in ages past, tell us that in successive periods, each consisting of about 26,000 years, each hemisphere, northern and southern, has been successively subject to repeated cyclical changes in temperature. There have been for the area which is now England many alternations of long periods of heat and cold. Whenever the area became warmer, the descendants of semi-tropical forms would gradually creep further and further north, whilst the descendants of cold-loving plants would retreat from the advancing temperature. *Vice versâ*, whenever the area became gradually colder, the heat-loving plants would, from one generation to another, retreat further and further south, whilst the cold-loving plants would return to the area from which their ancestors had been driven out. In each case there would be some lingering remnants of the retreating vegetation (though perhaps existing with diminished vigour), growing alongside of the earliest arrivals of the incoming vegetation. Such is a possible explanation of our finding these plant remains comingled together. It must, too, be borne in mind that it is not so much the mean temperature of a whole year which affects the possibility of plants growing in any locality, as the fact of what are the extremes of summer and winter temperature. For example, one place may have a mean winter temperature of 50°, and a summer one of 70°; while another place might have a mean winter temperature of 20°, and a summer one of 100°, and yet both have a mean *annual* temperature of 60°. In Cornwall the maiden-hair fern grows in sheltered localities, because the winter temperature never sinks to the point that would cause its destruction. Again, at that most charming spot in the west of Ireland, Glengariff, the arbutus still forms an abundant underwood; and the Irish filmy fern flourished in many favoured spots until quite recently, when the modern, too comfortable Eccles Hotel has retained tourists in the district, who have ruthlessly carried off, as reminiscences of a pleasant holiday, this which was one of the most attractive features to the botanists.



of MONOCOTYLEDONS, FROM THE LOWER BAGSHOT BEDS.
1, Fan Palm; 2, Smilax; 3, Feather Palm.

These facts, which seem so simple when laid out in diagrams, are the results of long-continued and careful work; but you may take my word for it, having enjoyed the during my holidays for many summers, that fossils is a fine, healthy and active exercise. this particular district, let me tell you some of nces. Fossils are not to be obtained here without hard work; the steep and crumbling cliffs have to be climbed, and most diligent search has to be made for indications of them. Fifty times, perhaps, the cliff may be laboriously scaled to examine what appears from the beach to be a promising-looking patch of clay, to result only in disappointment; either the clay turns out to be too sandy, and the impressions valueless; or it contains nothing; or it is found, accessible. But supposing well- reward the search, a secure footing has first to be cut with a light pickaxe; then the sands or clays overlying the leaf-bed have to be removed by spade and pick—real navvy's work this—then to get out blocks large enough to contain the palm-leaf shown in this drawing, which is only enlarged twice, the leaf-bed has to be undermined to a depth of five or six feet, a difficult operation requiring patience, and the then hanging mass of clay has to be cut off with the pick, being too plastic to break away by its own weight. When nearly cut through, it gradually breaks away, and falls gently on to the platform prepared for it underneath. The blocks thus obtained are sometimes too large for three or four men to tilt over. The method is then to leave them to dry, as when wet the clay will not split to disclose the leaves. It is then, I can assure you, that I esteem myself fortunate if some too curious excursionist, or enthusiastic townsman, does not arrive during my absence with a hammer to break the blocks up. So great has been the curiosity excited, that fossilizers have so far forgotten their sense of justice as to get up at daybreak to appropriate the result of my work had not the faithful coast-guardsmen, with a keener sense of justice, been near.

Wet weather of course puts a stop to operations, and buries the working in mud and sand, sometimes two or three feet deep even in a single night. When the workings are as far off from your headquarters as at Poole Harbour, and the specimens heavy, a boat is necessary to convey them home. The most enjoyable moments are, perhaps, those occupied in splitting the blocks, as one then shares what I should suppose to be the excitement of gold-workers, except that gold-finding must be more monotonous, as in this case no one can say what sort of treasure may reward us next. Anyhow, it is a recreation strongly to be recommended to those who like healthy exercise, freedom, and the sea.

[A large and heavy block of matrix was then split, in illustration of this part of the lecture, and a layer showing hundreds of leaves, exposed for the first time to view.]

I have now endeavoured to give you as accurately as I can, the absolute facts as far as we can learn them, respecting the conditions under which these beds were deposited, the sources from which the material was derived, and so far as we can tell, by comparison with existing vegetation, what were the trees of which these leaves are the records, and also the climatal conditions under which they grew. We may now, in conclusion, allow our imagination to come into play, a scientific use of the imagination, I hope it is, while we picture to ourselves the appearance of this area during the time these beds were being formed. The changing force of the streams and their directions varying from time to would, as we have already said, frequently undo th of accumulation which had been previously done.

We have reason to believe that there was here a width of valley closed in to the north by the chalk hills which are still represented by the chalk range of North Hampshire and Wiltshire, and on the south and east by accumulations forming the lagoon barrier of which I have spoken. The course of the stream was from west to east. To the east was the sea, to the west was the valley of the stream, about some of the conditions of which necessarily uncertain, in consequence of the changes from upheaval and denudation, which have extensively modified that district. When the streams were from ons swollen they moved along at a rapid ra away previously deposited beds and also coarse quartz grit and blocks, were not so violent then there were doubtless frequently repeated scenes such as I will now attempt to describe to you. In this ideal picture I have endeavoured to depict what I consider to have been the state of things. Here we have the valley of the river some six or seven miles broad. The streams reduced to streamlets meandering through dried and barren sand-banks. Among them are more elevated patches—islands, if we may use the term—islands standing up from the general expanse of sand, and in some cases actual islands in the sense that they were surrounded by water. Here and there pools of water, some almost stagnant, others fed by minute streamlets.

Looking at the scene from a southern standpoint we should see to the north the distant chalk range. Whilst along the shore of the opposite bank of the valley we could with some difficulty detect the various forms of vegetation, which we should see with greater clearness in the more immediate foreground. In this valley a singular stillness must have prevailed, as no trace of animal life whatever has been found, except a feather and a few insect wings blown in from the southern bank.

Of the following at least we are pretty sure, and of numerous others we can be almost sure, but there are indications of very many besides, the relationships of which are at present but imperfectly defined.

Here we should see the graceful fan-palm and the feather palms, adding softness to the view by their elegantly-curved and drooping leaves, laurel and dwarfed oak, stately beeches, clumps of feathery acacia, trellised and festooned with smilax, the trailing aroid, with its large and glossy foliage and an undergrowth of *Mimosa* and of cypress in the swampier ground, and variations in colour caused by the foliage of cinnamon and fig, and the ground clothed with ferns and sedges. On the barren sands of the distant valley are growing clumps of giant and weird-looking cactus. It is not difficult to picture to ourselves the view. (See Fig. 2.)

All this beauty is gone. We have nothing but these records of what must have been a view of great loveliness, which only the toil of the geologist can even faintly reproduce.

> "The hills are shadows, and they flow
> From form to form, and nothing stands;
> They melt like mist, the solid lands,
> Like clouds they shape themselves and go.
>
> "There rolls the deep where grew the tree.
> O Earth, what changes hast thou seen!
> There where the long street roars, hath been
> The stillness of the central sea."

THE REPORT ON THE AUSTRIAN "NOVARA" EXPEDITION

A FEW days ago Admiral v. Wüllerstorff Urbair, late Commander-in-Chief of the Austrian *Novara* Exploring Expedition, had an audience of the Emperor to present to his Majesty the final report on the scientific results of this great exploring cruise round the world. It has required about seventeen years' serious labour, and has cost nearly 13,000*l.* sterling to complete this important scientific work, embracing 18 vols. 4to. and 3 vols. 8vo., and containing the anthropological, botanical, geological, zoological, physico-nautical, statistico-commercial, medical, and descriptive parts.

The narrative of the expedition, written by Dr. Karl von Scherzer (an author also well known in England, and at present attached to the Austro-Hungarian Embassy in London), has met with such a success that five editions have been published and more than 29,000 copies sold.

The most interesting of the purely scientific publications is the geological part, by Dr. Hochstetter, which gives the most complete description of the geology of New Zealand, the author having been the first naturalist who thoroughly explored these antipodean islands, and he has carefully examined and described its gold and coal deposits. The statistico-commercial part, by Dr. Karl von Scherzer, has become quite a standard book on the Continent.

The price of the complete series being very high (391 florins, or nearly 40*l.* sterling), the Emperor has given permission that a considerable number of copies of this most valuable publication should be given away to public institutions and libraries in the empire, as well as in foreign countries, and as the *Novara* has met with a particularly kind reception in the British colonies, the libraries of these have been considered first in the list of recipients of this great national work, which is a monument of scientific investigation.

THE CYCLONE WAVE IN BENGAL

AN interesting correspondence on this subject has appeared in the *Times* during the last few days, evincing generally on the part of the correspondents an earnest effort to arouse the public mind to a sense of the necessity or something being done towards mitigating the calamitous results of such occurrences in the future. The subject being one that must sooner or later be faced, it is beside the question to point to the destructive flooding of the Thames as a proof that the Government of India does not differ greatly in such matters from similar authorities at home.

As regards the meteorology of this important question, three lines of inquiry stand prominently out as calling for special and extended investigation. The first of these is a thorough discussion of the storms of the Bay of Bengal, or a continuation of the work under this head which has been ably begun by Mr. Blanford and Mr. Willson. The second line of inquiry is the cause or causes which originate the cyclone wave and determine the course it takes—a subject on which we cannot be said to have any information at present, all that is or can be said being little more than unsatisfactory conjectures. To carry out these inquiries with the fulness and with the detail required to ensure a successful handling of the subject additional stations must be established and the taking of meteorological observations must be more extensively and frequently done than is now the practice on board the ships which navigate the Bay.

The third line of inquiry is the systematic inauguration of a meteorological survey of the Bay of Bengal and its shores, with a more strict reference to its storms, by having first-class meteorological stations established at Trincomalee, Madras, Vizagapatam, False Point, Saugor Island, Chittagong, Akyab, Cape Negrais, the Andaman and the Nicobar Islands, these stations having a full equipment of instruments, including in each case a continuously registering barometer and anemometer. With these instruments the law of the diurnal oscillation of the barometer and of the changes in the direction and velocity of the wind, including the variations with season, would become known, and any deviation therefrom which may happen to occur, could be telegraphed at once to the head office at Calcutta. It may be regarded as absolutely certain, that no long time would elapse before the nature of the disturbing force, cyclonic or otherwise, revealed by the anomalous readings of the barometer and anemometer would come to be correctly interpreted; and with the aid of frequent telegrams from the whole circuit of stations, so well interpreted that the superintendent at Calcutta would have no difficulty in localising the cyclone, its track and rate of progress would be so certainly known that warning could be sent to the coasts threatened by it.

This system of storm warnings must not be confounded with that practised in Great Britain, in which no refined system of observations is called into play, and in which no accurate knowledge of mean periodic changes is required. What is chiefly required in this country is a vigilant outlook for what may be called the grosser changes of atmospheric pressure and of the wind, and a very moderate knowledge of meteorology for their interpretation. So clearly is this the case that notwithstanding the great advances made by meteorology in recent years no progress has been made in this country in issuing warnings of the approach of storms, since the number of fresh gales (8 of Beaufort-scale) of which warnings have been sent are still somewhat under the percentage of success attained by Fitzroy in 1864.

But in India it is different. Any system of storm-warnings there, to be successful, must be based on a refined system of observation carried on at a considerable number of stations in such positions as we have pointed out—those positions being selected with special reference to this inquiry.

OUR ASTRONOMICAL COLUMN

AN OBSERVATORY ON ETNA.—Prof. Tacchini sends us a note read before the Accademia Gioenia on September 22, 1876, entitled, "Della convenienza ed utilità di erigere sull' Etna una Stazione Astronomico-Meteorologica," in which after describing his experiences during a brief ascent on September 15-16, he expresses his views with regard to the establishment and most desirable fitting of an observatory on the mountain to be mainly devoted to spectroscopic and meteorological observations.

Prof. Tacchini ascended on the morning of September 15 from Catania to the station occupied by a party of the English and American expeditions on the occasion of the total solar eclipse of December, 1870, and found there a diminution of temperature of 33° Centigrade. He had taken with him a Dollond-telescope of 3¼ inches aperture, a spectroscope of strong dispersion by Tauber, a small spectroscope of Jannsen, an aneroid barometer, thermometers, and a polariscope. At 10h. 30m. A.M., on the 16th, a few detached clouds only being present, he remarked that the blue of the sky was much deeper than at Palermo or Catania. The solar light had a special character, it seemed whiter and more tranquil, as though due to artificial illumination by magnesium. Viewing the sun rapidly with the naked eye, it was seen as a black disc surrounded by an aureola of limited extent, projected on the blue ground of the sky. On interposing an opaque body before the disc the aureola was seen better but always limited, and the pure blue sky terminated the same, which extended to rather more than half the solar radius; with the naked eye it was difficult to judge if the aureola was of equal breadth all round the disc, and the only thing well marked was the difference from the view obtained at the level of the sea; while the sky is ordinarily whitish about the sun, on Etna it remained blue, and the aureola acquired a better-defined contour. With a helioscope the aureola was much better seen, and its border appeared irregular, and as though it were rather more extended at four points, which, at noon, corresponded to the extremities of the vertical and horizontal diameters of the disc. At 3 P.M., after interruption from clouds which in passing rapidly at short intervals produced a striking effect by the formation of a stupendous series of coloured rings round the sun containing all the gradations of colour in the spectrum, a phenomenon new to Prof. Tacchini, the Tauber-spectroscope was applied to the telescope for examination of the solar spectrum, and the observer expresses his surprise at the fine definition of the lines and the extraordinary distinctness of the whole; the chromosphere was bright.

In the evening at 10h., the spectacle of the starlit sky was novel and enchanting. Sirius appeared to rival Venus, the finer constellations acquired an altogether special aspect, and the appearance of the Via Lactea was astounding. The image of the planet Saturn was admirable, and the peculiarities of the ring and belts were seen to much greater advantage than at Palermo, shortly before leaving. Venus afforded remarkable proof of the rare quality of the sky of Etna. The planet shone with a powerful light, which cast shadows during the ascent of the mountain; it scintillated frequently like a star. The telescope showed, on the northern part of the phase, an oblong space, less illuminated than the rest of the disc, which Prof. Tacchini says was "sicuramente una macchia del pianeta."

Spectroscopic observations were renewed on the following morning, when the sun had attained an altitude of 10°. The chromosphere was "magnificent;" the inversion of the magnesium and of 1474 was immediately evident, which was not seen at Palermo with the same telescope.

With regard to the proposed observatory which Prof. Tacchini is desirous should be an accomplished fact before the meeting of the scientific bodies at Rome, in September next, he proposes that it should be erected at the *Casina degl' Inglesi*, and should be named after Bellini, and that it should belong to the University of Catania. He suggests that it ought to be provided with a refractor of first-rate quality and of at least 16 centim. (about 6·3 inches) aperture, and he advises that while the meteorological instruments, which should be adapted to the requirements of the day, as indicated by the London Congress, would remain constantly at the Bellini Observatory, a duplicate mounting might be provided for the refractor at some spot within the University of Catania, with its proper dome, the other being fixed on Etna, so that while from June to the end of September astronomical observations could be carried on upon the mountain, during the winter they might be made at Catania, where the sky is a very good one; the astronomer would thus have only the object-glass with its tube to transport to and fro. Prof. Tacchini further suggests that accommodation for visitors should be provided, with the view to increasing their numbers, and that a certain payment should be made by them, to go towards the maintenance of the Observatory and its custodian.

We wish every success to the scheme thus energetically brought before the Italian authorities by Prof. Tacchini, and have no hesitation in predicting important gains to science from its adoption.

THE NEW STAR OF 1604.—The vicinity of this star's place deserves to be closely watched, as it appears by no means improbable that the object may be identified amongst the telescopic stars actually visible, by small fluctuations of brightness, which there are grounds for supposing to have been the case with the so-called new stars of Tycho Brahe and Anthelm.

The best position of Nova 1604, is no doubt that deduced by Prof. Schönfeld from the observations of David Fabricius, found in the *literæ mutuæ* in Fritsch's edition of Kepler's works. Fabricius measured the distance of the new star from ζ, η, [illegible] Ophiuchi, α Aquilæ, and α Scorpii, and the discussion of these measures leads to the following place for 1605·0, R.A. 256° 45′ 43″ or 17h. 7m. 2·9s., N.P.D. 111° 4′ 42″, with probable errors of ± 2·0s. and ± 0·65′; this position brought up to 1877·0 is R.A. 17h. 23m. 16s., N.P.D. 111° 22·4′. The nearest catalogued star is one of 8·9 mag. observed in Argelander's Southern Zones, No. 16872 of Oeltzen's reductions. Kepler's star precedes, according to Schönfeld's calculation, 25·3s., and is N. about 0·8′. There is a star 12·13 mag. preceding Argelander's star 18·8s., and 1·6′ to the south, suspiciously close to the recorded place, since the probable errors are no safe guide in such a case as this. Chacornac on Chart No. 52, has a tenth magnitude in about R.A. 17h. 21m. 50s., N.P.D. 111° 22′ for 1855, which is not now visible or was not last summer. But the locality requires a stricter and more systematic examination, which may be suggested to some one of our astronomical readers, who possess adequate optical power, when this region of the sky is favourably situated for observation.

METEOROLOGICAL NOTES

Storms and Floods of the Past Six Weeks.—An examination of the Daily Weather Maps published in different countries of Europe for this period is very instructive. The most common course taken by the winter storms of north-western Europe is an easterly or north-easterly one, and the tracks of their centres lie somewhere between Farö and Iceland. Hence the winter climate of the British Isles is characterised by south-westerly winds, and the relatively high temperature and humidity which they bring with them from the Atlantic. This state of things is occasionally varied by the centre of the storm passing in its easterly course across England, along the Channel, or over a track even still further south, resulting in easterly and northerly winds at places situated to the north of the centre track, with the probable accompaniments of sleet, snow, or hail, low temperatures, chill drizzling rains, and heavy seas. Since, however, the storm-centres usually soon pass on to eastward, the easterly winds accompanying them are generally not of long continuance. But during these past six weeks, notably from December 1 to 7, 16 to 24, and 31 to January 7, the cyclonic centres have had their course in the south, or to the south, of the British Islands, and consequently easterly and northerly winds have prevailed, particularly in the north of Great Britain. The cyclonic centres, instead of advancing, as ordinarily happens, to eastward, oscillated backwards and forwards—to eastward and then to westward, to north-westward, and then to south-eastward—being thus continually for days together in the south of the British Islands, and hence the persistency of the easterly winds for several days in succession in the north. Finally, since steep gradients prevailed frequently and for considerable periods from North Britain to Norway, the easterly winds acquired a violence, as well as a persistency, almost unprecedented, strewing the coasts with wrecks, and raising high tempestuous seas, which, particularly when conjoined with the high tides in the beginning of January, damaged harbours and other property to an extent fortunately of rare occurrence in these islands. As frequently happens, gradients were also steep and winds violent over the Channel and the south of England. The snow and rainfalls were also excessive, and blocking up of railways and river floodings, with the inconveniences and disasters attending them, were experienced in all parts except the north-west of Great Britain. At many places the rainfall of December was the heaviest ever recorded. The intimate bearing of the weather of Scandinavia and Lapland on that of Great Britain, and its great scientific importance in forecasting British weather—a point we have on various occasions insisted on in this journal—were several times conspicuously illustrated during the singular weather of these six weeks.

Physics of the Atlantic Ocean.—Dr. Buys Ballot has made a valuable contribution to the physics of the Atlantic Ocean in a paper just published on its mean monthly atmospheric pressure. The author wisely groups the observations for each degree of latitude along the outward and homeward bound routes of the Dutch ships on board which the observations were made. The extent and laboriousness of the work will be understood from the fact that for the North Atlantic alone, 175,003 observations have been discussed for the outward, and 163,418 for the homeward bound route. We shall take an early opportunity of reverting to the subject of this paper; in the meantime we content ourselves with heartily recommending the paper more particularly to seamen, from its great utility in navigation, seeing that it gives them the average barometric pressure each month for each degree along this great highway of commerce, which, when intelligently interpreted by the wind which happens to prevail at the time, puts them in possession of information, the importance of which it is impossible to over-estimate.

Weather Maps of Germany.—The Weather Maps of the *Deutsche Seewarte*, in the numbers for January, already received, give on a large scale the barometric curve and the hourly direction and force of the wind for the twenty-four hours previous, as recorded by the self-registering instruments at Hamburg. The value of such data in the study of the daily changes of the weather it is unnecessary to point out. This Office has also begun to publish monthly *résumés* of the weather of the Continent, of which those for January and February, 1876, have appeared, containing short papers by various well-known meteorologists, referring to the weather of the month; and the averages and extremes for the month are briefly but lucidly discussed for all the stations in Germany, and for many other stations in the countries adjoining. A valuable chart is given showing the tracks from day to day of all the European storms of the month.

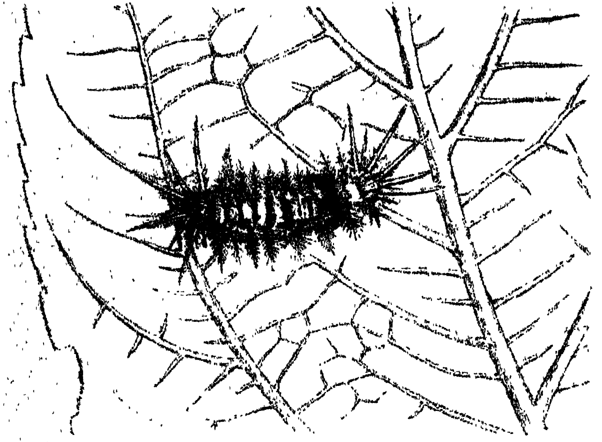
Thunderstorms in Central Europe.—It was recently shown by M. von Bezold that there is a double maximum in the frequency of summer thunderstorms in particular regions of central Europe. The results of further researches by others seem to point in many cases to a similar behaviour in hydrometeors generally. Thus a double periodicity in hailfall has been demonstrated by M. Prettner for Kärnthen and M. Fournet for the Rhone Valley. And more recently still (*Pogg. Ann.*), Dr. Hellman, having studied the rainfall in North Germany, is led to the following conclusions:—1. There is a double maximum in both the frequency and quantity of rain in the summer months in North Germany. 2. The first maximum falls, in the case of quantity of rain, in the beginning of the second half of June; that for frequency of rain in the beginning of June; the second maximum for both cases in the middle of August. 3. The first maximum is more intense in the case of frequency of rain, and weaker in the case of quantity. Dr. Hellmann offers an explanation of these phenomena, for which, however, we must refer to the original.

Sunspots and Weather.—Prof. Fritz, of Zurich, has shown from a comparison of annual meteorological statistics, that the years distinguished by a maximum of solar spots coincide very closely with those years marked by exceptionally severe hailstorms, and an unusual average height of the great rivers. This law is shown to be in accordance with observations made during the past century in all latitudes, the special periods occurring at intervals of eleven years.

BIOLOGICAL NOTES

Chemical Changes Observed during Progress of the Potato Disease.—The Rev. J. H. Jellett details the results of a series of experiments made to ascertain (1) whether there be any development of sugar during the progresss of the disease, and if so of what kind? (2) whether there be any perceptible change in the quantity of nitrogen? It would appear that the first stage of the disease in the tuber is marked by an increase in the quantity of the nitrogen, which seems to attain its greatest value before the stage of discoloration of the tuber. The same stage of the disease is also marked by the development of sugar, both glucose and sucrose. In the second stage of the disease, marked by a great increase in the discoloured part of the tuber, the part which remains apparently sound shows no increase of nitrogen, but a very considerable increase in the quantity of sugar, while in the discoloured part there is a diminution both in the percentage of nitrogen and of sugar. It will be remarked that the development of the sugar continues for a considerable time after the nitrogen has attained its maximum value. Mr. Jellett has no doubt that the whole of this sugar is formed by the conversion of the potato starch, though he is not aware that there is any known method by which starch can be made to pass into sucrose; possibly this effect may be produced by the presence of the fungus. (*Proc. R. Irish Acad.*, Vol. ii., Series ii. Science, January, 1877.)

COMMENSALISM AMONG CATERPILLARS.—The following extract from a letter from Fritz Müller, dated Itajahy, Brazil, October 22, has been sent us by his brother, Dr. Hermann Müller, of Lippstadt:—"I have lately become acquainted with an interesting case of commensalism in two caterpillars, of which I inclose a photograph taken by my friend, Scheidemantel. The larger caterpillar, with red head, protected by long branchy stinging-hairs or thorns, lives on mulberry and other trees. Like other caterpillars protected from enemies by odour, stinging-hairs, or otherwise, it sits on the upper side of the leaves, and is light-coloured, the head red, the hairs white. Across its back, between its thorns, there sits a small blackish caterpillar, protecting itself by the thorns of the large companion. I took off the small caterpillar from the large one, but it soon occupied again the same place. In order to take a photograph of it, the larger caterpillar was anæsthetised with ether; it recovered again somewhat, but after two days it died. The smaller caterpillar has now left its place and taken refuge on another caterpillar in the same box; on this it sits somewhat further forward, on the base of the abdomen. In its former host, the place where the small caterpillar sat looks pale, as if it had been scoured. The small caterpillar from above eats small holes in the leaf on which the larger one is sitting. As far as I know, no similar case has hitherto been observed."



BLISTERING BEETLES AS A CURE FOR HYDROPHOBIA.—M. de Saulcy, père, laid before a late meeting of the Entomological Society of France the *débris* of two species of beetles belonging to the Meloidæ (*Meloë tuccius* and *Mylabris tenebrosa*) which had been sent to him from Gabès, in Tunis, by M. de Chevarrier, and which constituted the medicine in use by the people of Amerna as a cure for hydrophobia. It is known under the name of *Dernona*, and is mentioned in several Arabian works on medicine. A portion about the weight of a grain of corn is given to the sufferer. The medical formula directs that it should be taken in some meat soup by the person bitten between the 21st and 27th day after the bite; if taken before or after these dates it will not effect a cure. The natives of Amerna seem to have great faith in this cure, and preserve the dried beetles as a treasure. It might be worth while to try a series of experiments on the use of the vesicating beetles in this terrible malady. But it should not be forgotten that so long ago as 1750, Linnæus, in his dissertation, "De Materia Medica in Regno Animali," suggested the employment in such cases of the common blistering beetle, and in 1856, when M. L. Fairmaire laid before the Entomological Society of France a brochure by M. Saint Hombourg on the treatment of hydrophobia by the administration of a species of Meloë, many of the members then present mentioned that this remedy was known for a very long time in Germany. (*Ann. Soc. Ent. France*, 27 Dec., 1875, *Bulletin*, p. clxiii.)

CARBONIFEROUS AMPHIBIA IN NOVA SCOTIA.—In the Carboniferous era many of the Sigillarian trees became partly embedded, and as they decayed their inner bark and woody axes crumbled away, leaving open holes on the surface of the ground into which were swept by water, or fell accidentally, the animals of the period together with vegetable *débris*. In this way successive layers of deposit, within the trunks of the trees, became stored with skeletons of Amphibian animals, snails, &c., which they have retained in an admirable state of preservation. Dr. J. W. Dawson, whose former investigations on this subject are well known by all palæontologists, has recently examined a fresh tree-stump about 2 feet high and 18 inches in diameter. In its interior were found no less than thirteen skeletons, more or less complete, belonging to six species, including *Hylerpeton dawsoni*, *Dendrerpeton acadianum*, *D. oweni*, a new species of *Hylerpeton* and *Hylonomus lyelli*. In the last part of the *American Journal of Science and Art*, Dr. Dawson has described these remains.

ACTION OF THE BRAIN.—At a recent *séance* of the French Academy, MM. Giacomini and Mosso presented the photograph of a woman who, from a syphilitic affection of the cranial walls, had lost a great part of the frontal and the two parietal bones. The movements of the brain of this woman (who is now completely cured) had been studied by the graphic method, one of M. Marey's tambours having been applied at the cranial aperture, and some remarkable results were obtained. The traces, which will appear in the *Archivio delle Scienze mediche*, prove that there are in the brain of man, even during the most absolute repose, three different kinds of movement:—1. *Pulsations*, which are produced at each contraction of the heart; 2. *Oscillations*, which correspond to the movements of the respiration; 3. *Undulations*, which are the largest curves, and are due to movements of the vessels during attention, cerebral activity, sleep, and other causes unknown; they might be called *spontaneous* movements of the vessels. The authors studied the relations between the movements of the brain, the heart contractions, the changes of volume of the forearm and the respiratory movements, by applying simultaneously with the arrangement just described, a pneumograph to the chest, and one of M. Mosso's plethysmographs to the forearm. The form of the brain-pulsation differs considerably from the tracing obtained from the fore-arm, or by means of a sphygmograph applied to an artery. During profound sleep, with snoring, there is considerable increase in the height of the cerebral pulsations, and the respiratory oscillations and the undulations are much more pronounced. Certain causes produce the same change of volume in the brain and in the extremities; others produce variations which are simultaneously in opposition in the brain and in the different parts of the body. The authors describe the effects of compressing the carotid and the jugular, the influence of bodily movements and intellectual labour, which are always reflected in a change of volume of the brain and therefore of its pulsations, and a number of interesting facts are elicited.

PAPUAN PLANTS.—So much still remains to be learned regarding the natural productions of New Guinea, that Baron von Mueller's Descriptive Notes on Papuan Plants, will contain much that is new to all botanists. Three successive papers have now been published under this title, the material being chiefly derived from the explorations of Macfarlane, Goldie, and D'Albertis. Von Mueller hopes that one or other of these energetic discoverers will shortly reach the hitherto unknown Alpine heights, which are likely to yield rich stores of endemic species.
